Foreword to the Third Edition

Are we alone? Already at the time of the Greek thinkers, more than two millennia ago, the question of the plurality of Worlds, even of the plurality of inhabited Worlds, was the subject of philosophical debates.

In the context of current research in astrobiology, it is impressive to reread this sentence of the philosopher Epicurus in the fourth century BC (341–270 BC): “Worlds are in an infinite number, some of them similar to our own one, some others being different . . . Living species, plants and all the other visible things could exist in some worlds and could not in others.” Exceptional vision: If the first part of this quotation has been fully proven by the discoveries of more than 5000 exoplanets, the second part is at the heart of the multi-disciplinary research conducted by many researchers of our time and the subject of this encyclopedia.

The interest for this question was not limited to antiquity, I like this quote from the philosopher and theologian Albertus Magnus (about 1200–1280):

Do there exist many worlds, or is there but a single world? This one of the most noble and exalted questions in the study of Nature.

During the last decades, the search for exoplanets has been rich in discoveries:

The frequency of planetary systems in our Galaxy, the diversity of these systems both by their architecture and by the physical nature of the exoplanets, the importance of orbital migration during the formation and evolution of these systems, and still the first steps for the determination of the compositions of planetary atmospheres . . . first step perhaps for the search of signatures of life.

Systematic searches for planetary systems, both on the ground using Doppler spectroscopy and in space with the detection of planetary transits, have shown that the vast majority (close to 100%!) of stars are hosts of such systems.

The detection bias of both techniques limits an accurate assessment of the number of rocky planets in the habitable zone of stars with masses not too different from that of the Earth's. Current estimates tell us that billions or even tens of billions of rocky planets, with a temperature adequate for the development of complex life chemistry, exist in our galaxy. Many observatories or space missions are focusing on the search for such planets among the stars closest to the Sun.

Planets in the habitable zones of very close stars have been detected. Let us mention for example the star systems Proxima Centauri and TRAPPIST-1. These stars of very small masses, of extremely low luminosity, have a habitable zone extremely close to the star, with orbital periods of a few days! Are these “Worlds” adequate for the development of life (synchronous rotation, intense flux of energetic particles?). Despite these uncertainties, these systems will probably be at the focus of coming research.

The search for true “earth twins,” these rocky planets in the habitable zone of stars with masses close to that of the Earth, is much more difficult, especially if we hope to discover one that presents transits. The amplitude of the variation of the stellar velocity wobble decreases strongly with the period. Worse the very small variations of the stellar velocity induced by the influence of the planet are dominated by the fluctuations produced by the magnetic activity of the star. Considerable efforts are made to improve the algorithms and to decrease the influence of the intrinsic stellar variability . . . hope is allowed.

Transmission spectroscopy during planetary transits has already allowed remarkable successes for our knowledge of the atmospheres of gas giant planets. The advent of very large telescopes both in space (JWST) and on the ground (e.g., the E-ELT in Chile and its 39 m diameter) should allow the first transmission spectroscopy of rocky planets.

For rocky planets on short period orbits other instrumental possibilities exist. By combining high spectral resolution and high spatial resolution (adaptive optics), it will be possible to study the light reflected by the planetary atmosphere.

If the past years were the golden age of the discovery of the diversity of planetary systems, the next decade will be the one of the atmospheres of exoplanets.

These few lines mention the contribution of astronomers (or even a small fraction of their efforts!). The research outlined here only concerns the search for planets likely to shelter life. But astrobiology is much broader: habitability, climatology, evolution of atmospheres, planetary interiors and their relation to atmospheres, chemistry, biology, and much more.

Unraveling the mystery of the composition of temperate rocky worlds is the first step toward maybe one day the detection of a signature of life. But what exactly are we looking for? This requires all the disciplines represented in this book.

A sufficiently rich subject . . . to justify an encyclopedia.

Preface

Where do we come from? Are we alone in the Universe? Where are we going? These are the questions addressed by astrobiology – the study of the origin, evolution, distribution, and the future of life in the Universe. The *Encyclopedia of Astrobiology* serves as the key to a common understanding of the astrobiology field among astronomers and astrophysicists, biologists and biochemists, chemists, geologists and geochemists, space scientists, historians of science, and others working in this interdisciplinary and rapidly expanding field.

Encyclopedias are unusual works. A quote from the prologue of one of the more famous early encyclopedias is instructive:

... the purpose of an encyclopedia is to collect knowledge disseminated around the globe; to set forth its general system to the men with whom we live, and transmit it to those who will come after us, so that the work of preceding centuries will not become useless to the centuries to come; and so that our offspring, becoming better instructed, will at the same time become more virtuous and happy, and that we should not die without having rendered a service to the human race in the future years to come. (Diderot and d'Alembert, *Encyclopédie* 1751)¹

Diderot and d'Alembert's eighteenth-century *Encyclopédie* was indeed ground-breaking, but perhaps more remarkable is the degree to which their description resembles the modern concept of genetic inheritance and natural selection: a civilization's accumulated knowledge being analogous to the traits encoded in an organism's time-tested DNA genome. In many ways, the *Encyclopédie* addressed the goals of astrobiology; between the lines, we find aspects of what makes biology biology.

Encyclopedias have now existed for approximately 2,000 years, the first being Pliny the Elder's *Naturalis Historia*, which was a compendium of the knowledge available to the citizen of the Roman Empire as documented by the first century AD.² It contained ~20,000 facts from 2,000 sources written by 200 authors. The present volume contains an unknown number of "facts" (indeed, some of the content will likely be proven false, as science is a living,

¹ A complete English and French version of the *Encyclopédie* can be found at <http://quod.lib.umich.edu/d/did/>

² For a complete English translation of Pliny the Elder's *The Natural History* by John Bostock see <http://www.perseus.tufts.edu/hopper/text?doc=Plin.+Nat.+toc&redirect=true>. A complete Latin version can be found at <http://www.perseus.tufts.edu/hopper/text?doc=Perseus:text:1999.02.0138:toc&redirect=true>

breathing accumulation of presently accepted knowledge, all subject to future revision), but it does include some 2,200 contributions, references, uncounted thousands of prior publications, and is written by 613 authors.

Modern encyclopedias are derived from the dictionaries of the eighteenth century. The two are similar in that both are arranged alphabetically and generally are the work of a team of expert contributors. They differ in that encyclopedias contain a deeper level of analysis of the included terms and attempt to cross-reference and place the assembled contents in a useful context. The first encyclopedias attempted to cover all human knowledge. This is now impossible for a printed work because the body of human knowledge is presently growing exponentially, with no end in sight. Encyclopedias now exist for almost every definable field of study. A field requires a certain degree of maturity to have an encyclopedia, and conversely, the publication of an encyclopedia commonly records the birth of a definable field of study. Astrobiology is an interdisciplinary field, spanning geology, chemistry, physics, astronomy, biology, engineering, computer science, and the history of science to name only the core fields of study.

While some of these fields of research are fairly well-mapped, many others are in rapid flux, and still others remain perennially enigmatic, awaiting future breakthroughs by the scientists of tomorrow. To this end, the *Encyclopedia of Astrobiology* is primarily aimed at younger scientists or scientists new to the field who wish to understand how their expertise coincides with current knowledge in other areas of study. It is hoped that the encyclopedia will serve to orient researchers to the current state of the art. A more in-depth discussion of many of the topic areas can be obtained by referring to college or graduate level texts or to the articles cited at the end of many of the entries.

Encyclopedias are snapshots of the state of knowledge at a particular time. In 1844, the book *Vestiges of the Natural History of Creation* was published anonymously (it was later found to have been written by Scottish publisher William Chambers) and created a public sensation.³ It offered a sweeping and very secular view of the development of the Solar System, stretching from the nebular hypothesis to the development of man. While primitive by modern standards (it was, after all, based on state-of-the-art early nineteenth-century science), it was in many ways remarkably similar to modern cosmology. In broad brushstrokes, it is the precursor to the worldview developed in Carl Sagan's *Cosmos*⁴ and the grand view of myriads of habitable planets implicit in the Drake equation. The implication of *Vestiges* was simply this: the Universe operates everywhere and at all times according to physical principles, and the evolution of matter is largely predictable and often progressive, proceeding from the simple to the complex.

Science has advanced dramatically since Chambers' book was published. It is truly a long way from Sir William Herschel's 40-ft telescope to the James

³Chambers R (1994) *Vestiges of the natural history of creation and other evolutionary writings*. University of Chicago Press

⁴*Cosmos* was a remarkable 13-part popular science series narrated by Carl Sagan which aired in 1980. Most if not all of the episodes can be viewed on line, and a book was spun off: Sagan C (1985) *Cosmos*. Ballantine Books

Webb Space Telescope,⁵ and from a Universe with seven known planets orbiting the Sun to one with more than 5,000 planets orbiting other stars. It is also a long way from the work of Black, Priestly, and Lavoisier⁶ to SELEX technology and high-throughput automated chemical screening and analysis, and from Lyell's *Principles of Geology*⁷ to plate tectonics and isotope geochemistry. Nonetheless, certain questions permeate the sciences across time and discipline. Woese's three domains of life⁸ are direct descendants of Linnaeus' early classification scheme, and both are attempts to unify and classify terrestrial organisms. Darwinism has offered an underlying mechanism for doing so that has allowed for unification of the assorted observations of the living world. However, the question of whether terrestrial life is unique in the universe has fascinated mankind for millennia.

It was not until 1959, when NASA began funding the search for life in the Universe in its Exobiology program, that we at last achieved the technological prowess to try to answer this question.⁹ The paleontologist George Gaylord Simpson famously noted shortly thereafter that Exobiology was a science "that has yet to demonstrate that its subject matter exists."

NASA's first exobiology grant was awarded to Wolf Vishniac for the construction of the Wolf Trap, a device for detecting bacteria on Mars. Due to size limitations, the device never flew, but various descendants have made the trip to Mars and returned various negative or tantalizingly ambiguous results. These results are, amusingly, either disappointingly or encouragingly ambiguous, depending on one's point of view. Despite remarkable progress in the sciences, humanity still has no answer to the question, "Are we alone?," though the question is in principle answerable. The search continues enthusiastically.

Why should we think there might be life elsewhere in the Universe? In 1960, the radio-astronomer Frank Drake developed his now-famous equation for estimating the number of communicating civilizations in the Galaxy:

$$N = R^* \times f_p \times n_e \times f_l \times f_i \times f_c \times L;$$

where N is the number of civilizations in our galaxy for which communication might be possible, R^* is the average rate of star formation per year, f_p is the

fraction of stars that have planets, n_c is the average number of planets that can support life per star with planets, f_l is the fraction of the planets that can support life on which life actually develops, f_i is the fraction of those on which intelligent life develops, f_c is the fraction of those on which civilizations communicate using detectable signals, and L is the length of time these civilizations communicate.

When Drake unveiled his equation in 1960 and estimated that there were maybe ten communicating civilizations in the Galaxy, few of the parameters were known with any certainty; the rate of star formation was perhaps the only solid measurable value. Fifty years later, the flourishing search for exoplanets has placed the focus on the second value. Notably, it now appears to be close to what Drake estimated. Thousands of exoplanets have been found around other stars, and current technology allows the observation of even small planets. Theory suggests that the fraction of stars with Earthlike planets may be close to Drake's initial estimate (see this Encyclopedia's entry for Eta-Earth). The least well-known value is the question of how difficult is it for life to begin (one of the "perennially enigmatic" facts mentioned above). Based on present knowledge, the fraction of planets on which life actually emerges (f_l) could be anywhere from very, very close to 0 or far closer to 1. We simply do not know. On the ends of the spectrum, the scientific community is divided into two equally "hunch"-based camps: first, life is inevitable and is a cosmic imperative (where conditions are appropriate) and, second, the origin of life requires such a concatenation of improbable events that it is the scientific equivalent of a miracle.

On the one planet we know of with life, our own, putative evidence in the form of isotopically light carbon appears in the earliest known sedimentary rocks, suggesting life emerged relatively early in the history of the planet, although we do not know whether this took place 100 years or 700 million years after the planet formed. This implies that either something extraordinary happened on Earth, or that the origin of life is a mundane phenomenon on young planets, given appropriate chemistry, environmental conditions, and enough time. Radioastronomy has provided a glimpse of the chemical inventory of the cosmos which does appear to be universal. Spectral signatures of a veritable zoo of organic compounds suggest that the Universe is strewn with the potential precursors of life. Organic carbon (in the form of carbon monoxide) has now been observed more than 13 billion years ago, only some 700 million years after the birth of the Universe in the Big Bang. The picture emerging, reminiscent of Chambers' universe, is that physics and chemistry are the same everywhere in the Universe, and that the Earth, although remarkable in many respects, may not be unique.

As in any factorial equation, the most important values are the ones with the largest uncertainty. Two approaches could shed light on the " f_l problem": the duplication of the process in the laboratory or the discovery of life on another planet. It is difficult to say whether the first approach will ever succeed to anyone's complete satisfaction, given that the origin of life on Earth was a historical event that happened when no one was around to witness it. The second approach, while fraught with technological difficulties, is perhaps more promising. To that end, numerous instruments and space missions have been designed and launched to explore the Solar System and beyond. The spectral

signatures of planets around nearby stars are being monitored for the characteristic signs of life such as the signature of disequilibrium chemistry in the form of the presence in their atmospheres of both oxidized and reduced gases.

While the answers to the vast questions that define astrobiology as a field of study are unclear, it is evident that answering them will require an interdisciplinary effort, stretching across international borders. One is hesitant to speculate what the answer to the question “Are we alone?” will ultimately be. As good scientists, we should probably withhold judgment until the data are in. As better scientists, we must join hands and find the data. The editors of the *Encyclopedia of Astrobiology* hope that this volume will contribute to this effort.

Since the field of astrobiology continues to expand at a rapid rate, the editors of the *Encyclopedia of Astrobiology* have decided that a new, Third Edition, is needed to update the Second Edition, which was published in 2015. The present edition includes more than 100 new entries, as well as updates for almost half of the already existing entries. The exciting new scientific results include the discovery of thousands of new exoplanets; data from a number of new spacecraft exploring the Solar System’s planets, satellites, and small bodies such as asteroids and comets; new isotopic data that radically change our understanding of the formation of the Solar System in general and the early earth in particular; the identification of increasingly complex organic molecules in space and in protoplanetary disks; new techniques and discoveries in prebiotic chemistry; novel efficient methodologies to generate genomic information in phylogeny and evolution; the characterization of new extreme environments and the isolation of previously unknown microorganisms; and the development of a next generation of facilities for sample analysis, sample curation, planetary simulation environments, and remote observations from the ground. Moreover, this new edition includes new entries in the history, philosophy, and sociology of astrobiology. We believe that both new and experienced researchers as well as graduate students – either in the adjacent fields of astrobiology or those new to the subject – will appreciate this reference work during their quest to understand the whole picture. To aid this process, this edition includes a Topical Map, broken down by research area, which nicely illustrates the breadth and the depth of the field of astrobiology. Although members of the different disciplines commonly employ their own terminology and technical language, here we have made a special effort to eliminate specialized jargon and overtechnical terms from the Encyclopedia. Synonyms and keywords from the previous editions have been carefully revisited.

Both the carefully selected group of active researchers contributing to this work as well as the expert field editors hope that this new edition will be valuable to the scientific community and accelerate the interdisciplinary advance of astrobiology.

The Editors

Acknowledgments

A brief note is warranted about how we constructed the Encyclopedia. A glossary of terms was first compiled by a team of experts in each field. It was then cross-referenced between fields to check for conceptual overlap and was then both expanded and pared down to produce a consensus entry list.

Authors with peer-recognized contributions to their fields of study were then invited to contribute entries appropriate to their expertise. After a final draft was submitted, entries were proofread and vetted for scientific accuracy and readability by a team of field editors and then edited and modified to be accessible by a reader with general knowledge of college-level science. Finally, the entries were cross-referenced and edited for stylistic consistency and ease of reading.

The editors would like to sincerely thank all the authors of the content of the Encyclopedia for their efforts and understanding throughout the long and at times difficult triple review process. We are particularly grateful to those who also accepted to act as non-specialist reviewers for fields other than their own.

We would also like to thank several people who, although not all were authors, served as external reviewers for a significant number of entries: Maxence Claeys (CEA, France), Carlos Garcia-Ferris (Universitat de València, Spain), David Hochberg (CAB, Madrid, Spain), Pierre Léna (Académie des Sciences, Paris, France), Susan Leschine (University of Massachusetts, Amherst, USA), and Jean Vandenhaute (University of Namur, Belgium).

We express our gratitude to our respective institutions, especially those who facilitated and aided in the organization and funding of editorial meetings: Centre National de la Recherche Scientifique (CNRS, France), Centre National d'Études Spatiales (CNES, France), Laboratoire d'Astrophysique de Bordeaux (France), Université de Bordeaux (France), GEOTOP Research Center for Geochemistry and Geodynamics (Université de Québec à Montréal, Canada), Natural Sciences and Engineering Research Council of Canada, European Science Foundation (Archean Environment Research Networking Program), Centro de Astrobiología (CAB, INTA-CSIC, Madrid, Spain), Universidad Autónoma de Madrid, NASA Goddard Space Flight Center Cooperative Agreement NNX09AH33A with the University of Massachusetts. This work was also supported by the European COST Action TD 1308 "Origins and evolution of life on Earth and in the Universe" and the Erasmus + European Astrobiology Campus.

Last, but certainly not least, we express our sincere appreciation to the editorial staff of Springer, in particular Saskia Ellis and Ramon Khanna who lent technical and administrative support throughout the entire process.

About the Editors-in-Chief

Muriel Gargaud is a Senior Scientist at CNRS (Centre National de la Recherche Scientifique) – Université de Bordeaux, France. She is an enthusiastic and experienced editor who has proven in various Astrobiology projects that she can manage a large number of editors and authors and deliver an excellent publication. She is presently the Vice-President of the European Astrobiology Institute.

William Irvine was President of the Commission on Bioastronomy of the International Astronomical Union. His research activity is concentrated in two areas: the chemistry of dense interstellar clouds and the physics and chemistry of comets. He collaborated with various NASA astrobiology working groups and is the author of more than 200 scientific articles.

Definition

51 Pegasi b is an extrasolar planet orbiting the solar-type star 51 Pegasi.

History

51 Pegasi b is the first Jupiter-type planet, with a minimum mass slightly smaller than half of that of Jupiter, discovered around a sunlike star. It was detected by ► [radial-velocity](#) observations obtained with the Elodie ► [spectrometer](#) on the 1.93-m telescope at the Observatoire de Haute Provence in France (Mayor and Queloz 1995). The extraordinarily short ► [period](#) of 4.230785 ± 0.000036 days was completely unexpected for a planet with a mass close to that of

Jupiter and led to some initial skepticism that the unseen companion of 51 Pegasi could be a gas ► [giant planet](#) (e.g., Gray 1997). However, the subsequent announcement of several other ► [radial-velocity planet](#) candidates soon convinced most people of the reality of ► [extrasolar planets](#). This historic discovery and the subsequent emergence of the vibrant field of exoplanetology allowed Michel Mayor and Didier Queloz to receive the Nobel Prize of Physics in 2019.

Overview

51 Pegasi is classified as a G dwarf similar to the Sun but slightly cooler, at a distance of 15.6 parsecs (50.9 light years). A periodic variation in the ► [radial velocity](#) of the star indicates an unseen companion with minimum mass of 0.472 ± 0.039 Jupiter masses, if the orbit is viewed edge-on, but the actual orbital inclination is not well established. The ► [orbit](#) is nearly circular, with an ► [eccentricity](#) of 0.013 ± 0.012 , presumably the result of circularization by tidal forces. The proximity of the planet to its star, 20 times closer than the Earth to the Sun, implies a temperature on the order of 1200 K. 51 Pegasi b is the prototype for a population of ► [hot Jupiters](#) that probably formed much farther from their parent stars, where conditions were cool enough for a gas giant planet

to form, followed by migration into a much tighter orbit around the host star.

Definition

55 Cancri is a bright ($V = 5.95$), nearby ($D = 12.3$ pc) G8V star part of a resolved binary system with a mid M-dwarf companion located at a projected separation of 1062 AU. Five exoplanets orbiting 55 Cancri are currently known. The properties of the planets in the 55 Cancri system are very diverse, with masses ranging between 8 Earth masses and 3 Jupiter masses and orbital periods as

short as 18 h and as long as 15 years. While all five planets have been discovered using the radial-velocity technique, the innermost one (55 Cancri e) has been found to transit its host star, providing additional insights into the nature of this extreme super-Earth.

History

The first exoplanet discovered in the system was 55 Cancri b (Butler et al. 1997), a Jupiter-mass companion on a 15-day orbit, which was published 2 years after the announcement of the first exoplanet orbiting a sun-like star (51 Pegasi b). Two more, longer-period planets orbiting 55 Cancri (c and d) were announced shortly thereafter (Marcy 2002). The discovery of the once smallest known exoplanet at the time, 55 Cancri e, was published by McArthur (2004), which rendered 55 Cancri the most populated planetary system at the time. With a published orbital period of 2.8 days and a minimum mass of 14 Earth masses, the discovery of 55 Cancri e prompted independent analyses of the radial-velocity dataset on which the announcement was based. In 2005, Wisdom found evidence for a Neptune-mass planet on a 260-day orbital period but also questioned whether the 2.8-day signal of 55 Cancri e could be an alias of the 44-day planet c. Fischer (2008) confirmed both the presence of a planet at 260 days (55 Cancri f) and the 2.8-day period of 55 Cancri e. Two years later, Dawson and Fabrycky (2010) found that the 2.8-day periodicity signal was in fact an alias of a significantly shorter 18-h (0.74 days) orbital period companion with a minimum mass of 8.2 Earth masses. A confirmation of this late reanalysis came a few months afterward with the transit discovery of 55 Cancri e (Winn 2011; Demory 2011), which eventually resulted in a refined radius of $1.88 \pm 0.03 R_{\text{Earth}}$ and a density of $6.7 \pm 0.4 \text{ g/cm}^3$ (Bourrier 2018).

Overview

The super-Earth 55 Cancri e has attracted considerable attention compared to the other planets of

the system because of several striking characteristics. First, it is one of the largest and most-massive exoplanets with orbital periods less than 1 day (Sanchis-Ojeda et al. 2014). Second, 55 Cancri e is located right at the upper edge of the so-called “radius valley” (Owen and Wu 2013; Fulton 2017) that separates super-Earths with negligible atmospheres to those with massive H/He envelopes. Therefore the innermost planet of the 55 Cancri system is key in better understanding the formation and evolution pathways of small close-in exoplanets through constraints on its bulk structure and atmospheric properties.

Thanks to the brightness of its host star, multiple observations of 55 Cancri e have been gathered from the extreme UV to the mid-infrared in the past decade. Despite these efforts, the nature of this super-Earth has not been entirely elucidated yet. Among the most notable conundra lie the interannual observations obtained with the MOST satellite in the visible, which have revealed a large amplitude modulation (Sulis 2019) phased on 55 Cancri e’s orbital period that is an order of magnitude larger than expected from the planet’s elevated dayside temperature (~2400 K). Another surprising observation is the variability of 55 Cancri e’s occultation signal measured by the Spitzer Space Telescope in the infrared (Demory et al. 2016a; Tamburo et al. 2018). The planetary thermal phase-curve obtained with the same facility (Demory et al. 2016b) revealed an Eastward offset suggestive of a significant atmosphere (Angelo and Hu 2017; Hammond and Pierrehumbert 2017). High-resolution spectroscopy observations of 55 Cancri e have shown tentative detection of neutral Sodium and singly ionized calcium lines, which may be the signpost of an exosphere. Ultraviolet observations gathered with the Hubble Space Telescope have further shown variability in several emission lines, possibly resulting from interactions between 55 Cancri e and the stellar corona (Bourrier 2018).

It has recently been shown that 55 Cancri e was orbiting inside the Alfvén surface of the host star stellar wind (Folsom 2020), which motivates a better accounting of potential star-planet interactions in the system. An ongoing monitoring of 55 Cancri with the CHEOPS satellite (Benz 2020) should soon reveal the

extent of the phase modulation variability observed in the visible and, hopefully, pinpoint its origin and unveil the nature of the enigmatic 55 Cancri e.

Definition

AbGradE is an independent association, initiated by the European Astrobiology Network Association (EANA), which promotes scientific networking primarily among PhD students and postdoctoral researchers in Europe. A principal activity of AbGradE is organizing biennial symposia in astrobiology, with the first symposium taking place in Edinburgh in 2014 and the second in Athens in 2016. In the intervening years, 1 day workshops are organized, for example, on “mission proposal writing” in 2015 at the European Space Research and Technology Centre (ESTEC) in the Netherlands.

Abiogenesis

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, BPNantes, France

Definition

Thomas Huxley (1825–1895) used the term *abiogenesis* in an important text published in 1870. He strictly made the difference between spontaneous generation, which he did not accept, and the

possibility of the evolution of matter from inert to living, without any influence of life.

Since the end of the nineteenth century, *evolutive abiogenesis* means increasing complexity and evolution of matter from inert to living state in the abiotic context of evolution of primitive Earth.

Abiotic

David C. Fernandez-Remolar
State Key Laboratory of Lunar and Planetary
Sciences, Macau University of Science and
Technology, Taipa, China
CNSA Macau Center for Space Exploration and
Science, Macau, PR China

Definition

Abiotic refers to the ongoing physical and chemical processes in natural environments driven by different mechanisms that deviate from any biological activity. Although primary physical and chemical cycles on Earth can hardly escape the activity of the biosphere, some processes do not depend on biological activities. For example, this is the case of hydrothermal deposits resulting from reactions equilibrated at high temperature and driven by the circulation of hot fluids commonly through a silica-rich host rock. Under those conditions, the redox, volatile fugacity, and mineral saturation are fully conducted by physical and chemical processes that are independent of the biological processes. Interestingly, while the

hydrothermal processes are mostly unbound from the biological activity, they can produce organic compounds (McCollom and Seewald 2007) or replicate chemical reactions that are mimicked some way by some metabolic pathways (Huber and Wächtershäuser 1997). In analogous conditions, different organics could also be produced through the impact of large planetary impact of chondritic bodies on the Early Earth oceanic masses (rc). Therefore, some abiotic pathways have likely been essential to originate the primary biochemical materials and pathways that might have driven the emergence of life on Earth. Some abiotic processes are involved in producing surface oxidants through photochemical reactions in planet atmospheres, as proposed to explain the presence of different inorganic compounds on Mars like sulfates and perchlorates (Catling et al. 2010; Hurowitz et al. 2010). Those processes could be also associated with the production of different organic compounds showing a high oxidation degree like oxalates (Cheng et al. 2016). Furthermore, the detection of different organics in different planetary surfaces strongly support that they are actively produced or have been produced through abiotic processes in far different planetary bodies of the Solar System (e.g., Mars, Titan, Enceladus, etc.) since its formation (Eigenbrode et al. 2018; Waite et al. 2005). Different abiotic pathways (thermal, radiolytic, or photochemical) are essential to promote the emergence of a chemical disequilibrium and production of essential chemicals for life to transform a given area of the Universe into potentially habitable.

Synonyms

Abiogenic photosynthesis; Prebiotic photosynthesis

Definition

Abiotic or abiogenic photosynthesis is the synthesis of organic compounds with the aid of radiant energy and various inorganic or organic catalysts.

History

In September 1912, Benjamin Moore suggested at a discussion on the origin of life, held by the joint sections of Zoology and Physiology of the British Association for the Advancement of Science, that “the first step towards the origin of life must have been the synthesis of organic matter from inorganic by the agency of inorganic colloids acting as transformers or catalysts for radiant solar energy” (Moore and Webster 1913).

Overview

In spite of Haldane’s well-known idea that UV light may have served as a driving force for formation of the first viruslike organisms (Haldane 1929), the idea of directly driving abiogenesis by solar energy had not won much support at that time, despite the fact that the Sun is by far the most powerful energy source on Earth. The limited acceptance of the idea was partly due to the low quantum yield of abiotic photosynthetic reactions and the poor reproducibility of experimental results. Abiotic photoproduction of hydrogen, in the presence of ions of divalent iron, has been observed (Mauzerall et al. 1993). It has been shown atmospheric photochemistry can produce aldehydes from CO (Bar-Nun and Chang 1983). Only in the 1980s, were robust procedures of producing colloidal nanoparticles of photoactive semiconductors, such as zinc sulfide (ZnS) or cadmium sulfide (CdS), developed (Henglein 1984). These particles (see Fig. 1), due to their

A

Abiotic Photosynthesis, Fig. 1 Abiogenic photosynthesis on the primordial Earth. *Left panel:* light-induced reactions in a ZnS particle combined with an energy diagram. The absorption of a UV quantum by a minute crystal of ZnS, an *n*-type semiconductor, leads to the separation of electric charges and to the transition of the excited electrons into the conducting zone. The electrons can migrate inside the crystal until they are trapped at the surface,

where they can be picked up by appropriate acceptors, e.g., molecules of CO_2 . The residual electron vacancies (holes) are initially reduced by the S^{2-} ions of the crystal, which then eventually can be replenished by external electron donors, e.g., H_2S (cf with the mechanism of anoxygenic photosynthesis). *Right panel:* the precipitation of ZnS particles (gray dots) around a Hadean continental hot spring (Figure from Mulkidjanian 2009)

high surface-to-volume ratio, provided experimental systems in which the photoreduction of CO_2 to diverse organic compounds could be studied. The photoreduction proceeded with high and reproducible quantum yield (up to 80% for CO_2 reduction to formate at the surface of colloidal ZnS particles (Henglein 1984)). Recent studies have demonstrated high-yielding ZnS- and MnS-mediated photosynthesis under simulated primeval conditions (Zhang et al. 2004, 2007; Guzman and Martin 2009). In the modern oceans, ZnS and MnS are found at the sites of geothermal activity, where minute particles of these minerals continuously precipitate around hot, deep-sea hydrothermal vents; thereby, particles of ZnS and MnS, slowly precipitating sulfides, make rings around black throats of such vents that are covered by promptly precipitated particles of FeS (Tivey 2007). On the primordial Earth, hot metal-enriched geothermal fluids and vapor may have discharged to the surface of the first continents, so that particles of ZnS and MnS could have precipitated within regions exposed to solar radiation (Mulkidjanian 2009). These sulfide minerals could have been

present in shallow waters (Guzman and Martin 2009) and should have precipitated around continental thermal springs (Mulkidjanian 2009). Since Zn^{2+} ions are much more volatile than Fe^{2+} ions, the vapor of continental geothermal systems would be particularly enriched in ZnS (Mulkidjanian et al. 2012). On the primordial Earth, ZnS could not be oxidized by atmospheric oxygen, so that photosynthesizing and habitable rings may have persisted around terrestrial thermal springs and fumaroles. The development of the first life forms within photosynthesizing, ZnS-containing precipitates at such anoxic geothermal fields, where Zn^{2+} ions would be continuously released as by-products of abiogenic photosynthesis, might explain cellular enrichments in Zn^{2+} , the equilibrium concentration of which in the primordial ocean should have been extremely low (Mulkidjanian and Galperin 2009; Mulkidjanian et al. 2012). Several proteins shared by all extant organisms and believed to form the core of the last universal common ancestor (LUCA) are particularly enriched in Zn and Mn; this may also support the notion of a role for

abiogenic photosynthesis in the earliest stages of evolution (Mulkey and Galperin 2009; Mulkey et al. 2012). Since these ubiquitous proteins are depleted in iron, it remains to be established whether and to what extent iron (II), the predominant transition metal in geothermal exhalations, was involved in abiogenic photosynthesis. It has also been shown that titanium dioxide particles can drive photosynthetic organic chemistry inside cell membrane-like vesicles (Summers et al. 2009). Titanium dioxide (both rutile and anatase) particles could have been formed by precipitation or released (directly or from alteration of other titanium minerals) by weathering. This energy transduction could have provided pathways to new compounds in a prebiotic system or support early biochemical reactions.

Synonyms

Non-enzymatic rearrangement; Primitive RNA catalysis; Self-catalytic activity

Definition

The RNA world hypothesis (Gilbert 1986) states that systems based on an RNA genome and RNA catalysts preceded current forms of life and several model systems have been described for auto-replication (Cech 1986; Meyer et al. 2012) and metabolism (Nissen et al. 2000). According to this model, long catalytically active RNA molecules (*ribozymes*) had to evolve from short RNA fragments through the reactions of cleavage and/or intermolecular ligation (named collectively “recombination”). Both reactions involve transesterification, which implies the involvement of 2'-OH group of ribose in the cleavage site for the ester bond transfer. This is the main reason for most likely participation of RNA rather than DNA in evolution under prebiotic conditions.

History (Optional)

RNA nonenzymatic recombination reactions are of great interest within the hypothesis of the “RNA world” (Gilbert 1986) which argues that, at some stage of prebiotic life development, proteins were not yet engaged in biochemical reactions and RNA carried out both the information storage task and the full range of catalytic roles necessary in primitive self-replicating systems. In the same year of the pivotal paper of Gilbert, Cech (1986) described an RNA enzyme able to convert pentacytidylic acid (pC₅) to poly(C) with multiple turnover, using the same recombination activity that it employs in the self-splicing and autocyclization reactions (Kruger et al. 1982). This RNA enzyme or *ribozyme* acts as a poly(C)polymerase, synthesizing RNA in a 5'-to-3' direction. Using the method known as in vitro selection (Tuerk and Gold 1990; Ellington and Szostak 1990) more than a dozen research groups

have demonstrated that ribozymes have the potential to catalyze the diverse chemical reactions required to sustain a metabolism, reactions that include RNA ligation, peptide coupling, Diels-Alder bond formation, redox reactions, decarboxylation, and transphosphorylation (reviewed in Chen et al. 2007). With the advancement of knowledge in nonenzymatic oligomerization (Lohrmann et al. 1980), recombination, the swapping of large blocks of polymeric information through near energy-neutral reactions, offered a facile means to accomplish a supply of polymers long enough to possess phenotypic function and diverse enough to provide raw material for natural Darwinian selection (Riley and Lehman 2003).

Overview

The origin of life journey may have started with chemical replication of simple linear polymers. Molecular variants capable of faster replication would come to dominate a population, and the development of cycles in which templates could foster one another's replication would have led to increasingly complex replicators and from thence to the initial genomes. The appearance of long RNA molecules under prebiotic conditions is not self-evident. Recombination seems to be a plausible way of creating RNA diversity, resulting in the appearance of functional RNAs, capable of self-replication. The nonenzymatic polymerization process, studied for decades (Yadav et al. 2020), seems to be slow, so that an equilibrium between synthesis and degradation of the polymer would rapidly be reached, preventing the accumulation of sufficiently long (pre)genetically meaningful information. Polymer elongation by successive condensation steps adding one monomer at the time is not a likely mechanism for the accumulation of (pre) genetic information. A series of studies published by Lehman's group revealed fascinating phenomena of RNA recombination. They demonstrated that four special RNA fragments of 40–60 nucleotides can self-assemble with the formation of the *Azoarcus* intron I, the latter, in

turn, catalyzes RNA oligonucleotide recombination (Riley and Lehman 2003; Hayden et al. 2005). Moreover, motivated by the discovery that RNA oligomers stored for long periods of time in the freezer expand their lengths, they systematically investigated RNA–RNA recombination processes and discovered at least three new mechanisms. In these, one RNA oligomer acts as a splint to catalyze the hybridization of two other oligomers and facilitates the attack of a 5'-OH, a 3'-OH, or a 2'-OH nucleophile of one oligomer onto a target atom of another (Smail et al. 2019).

Pino et al. (2008) observed RNA multimerization by simply leaving ribooligonucleotides in water in the presence of an adenine-based nucleotide cofactor (Fig. 1, panel

A). The reaction was dependent upon time, type of cofactor, oligonucleotide length and sequence, temperature, and pH through a mechanism of a double-stranded structure as the initial step of the ligation reaction (Pino et al. 2011a). Sequence complementarity-driven terminal ligation of polyG on polyC and, complementarily, of polyC on polyG was demonstrated to occur non-enzymatically in water in the absence of any added organic or inorganic cofactor (Pino et al. 2011b) (Fig. 1, panel B).

In the same paper, a reaction consisting of the ligation of cytosine-containing mixed sequences with no internal sequence complementarity in the presence of a cyclic guanosine nucleotide was described. Both terminal ligation and terminal growth result in the generation

Abiotic Recombination, Fig. 1 Abiotic synthesis of oligonucleotides

Panel A: Formation of dimer- and tetramer-sized multimers from a γ - ^{32}P 5'-labeled A_{23} -mer as a function of different cofactors. First lane: the untreated (U) sample. RNA monomer was reacted in Tris-HCl- buffered water at 60 °C at pH 6.2 for 12 hrs. Active ligation was favored by 3'-AMP and 5'-AMP. Adenine, adenosine, ADP, and ATP only showed minor stimulation of the reaction.

Panel B: Terminal ligation of poly G_{24} to poly C_{24} . Poly G_{24} γ - ^{32}P -phosphorylated at the 5'-end was reacted with increasing amounts of unphosphorylated poly C_{24} . The following cartoons are shown at the right: G sequences (blue), C sequences (green), 3'-extremity (black), 5'-extremity (red), filled dots for [^{32}P]phosphate groups. The G_{24} - C_{24} dimer is shown. The reaction was conducted for 30 min at 60 °C in water (pH 5.3).

A

Abiotic Recombination, Fig. 2 Ligation-cleavage mechanism

Simultaneous ligation-cleavage mechanism shown on the example of the reaction between C_{24} and 5'-phosphorylated G_{24} . On the left: ligation assuming loop formation at the 3'-end of C_{24} and attack at the phosphorylated 5'-end of G_{24} leading to the formation of

$C_{24}G_{24}$. On the right: simultaneous cleavage reaction initiated by the attack of the 3'-end of C_{24} at the last but one phosphate of the 5'-phosphorylated G_{24} . The products of this reaction are $C_{24}G_{23}$ and 5'-phosphorylated guanosine-phosphate, which readily combines with C_{24} leading to the formation of $C_{24}pG$. (From: Pino et al. 2013).

of complex and controlled sequence combinations dictated by the sequences themselves. A reaction carried out by nonenzymatically generated oligoG RNAs when challenged with a base-pair complementary sequence is also possible (Pino et al. 2013). In this reaction (dubbed LIC: Ligation following Intermolecular Cleavage) two complementary sequences ligate and self-cleave through the nucleophilic attack of an acceptor 3'-hydroxyl group on the phosphorus of a donor 3',5' phosphodiester bond. The mechanism of the LIC reaction requires a tetraloop-like transient but sufficiently stable overhang structure due to imperfect pairing of the donor and acceptor strands (Šponer et al. 2016) (Fig. 2).

Staroseletz et al. (2018) explored the RNA recombination process by modeling it with a simple system which included two RNA fragments and Mg^{2+} as a catalyst, showing that oligomers which form the most stable intermediate complex (due to formation of a duplex with a template or some kind of intramolecular duplex) and achieve the optimal orientation of the ligation reacting groups (2',3'-cyclophosphate and 5'-OH) will be the most selected. RNA ligation

occurs mostly in the internal loops, bulge-loops, and the end of stem structures, definitively indicating that both RNA sequence and structure play a role in the evolution of the genetic material.

Definition

In geochronology, the “absolute age” of a rock is the age obtained from the measurement of the spontaneous decay of radioactive nuclides contained in the rock, or its constituent minerals, into their radiogenic daughter isotopes. It differs from the “relative age” of a rock, which is determined from spatial relations between rock formations (stratigraphy), giving only qualitative information on the period when the rock formed.

History

Relative dating of rocks is a method known since the foundation of the principles of stratigraphy by Nicolas Steno (1638–1686), a Danish scientist and Catholic Bishop who was a pioneer in both anatomy and geology. In his major contribution to geology – *Dissertationis prodromus* of 1669 – Steno is credited with three of the five defining principles of stratigraphy, the Earth science’ discipline which studies the order and relative position of geological strata of rocks and their relation to the geological timescale. James Hutton, considered the father of modern geology, later introduced the two remaining principles of stratigraphy. It is only from the beginning of the twentieth century, with the discovery of the radioactivity, that absolute dating of rocks was made possible. The first radiometric dating of rocks and the first absolute geological timescale was proposed by a young brilliant English scholar, Arthur Holmes (1890–1965). In his famous text, “The age of the Earth” published in 1913, he presents the first absolute rock dating using different methods (U-⁴He, U-Pb method) and measured ages that spanned from the Archean (dated at 710 Ma against 4–2.5 Ga today) to the Pleistocene (1 Ma). Holmes is thus considered the father of the geochronology.

Overview

The relative age of rock strata is usually determined based on their spatial relationships. These relationships are governed by the five principles of

stratigraphy which can be resumed as follows: (1) the *Principle of Superposition*, which states that in a sequence of strata, any stratum is younger than the sequence of strata on which it rests, and is older than the strata that rest upon it; (2) the *Principle of Initial Horizontality* which states that strata are deposited horizontally and then deformed later; (3) the *Principle of Strata Continuity*, which states that strata can be assumed to have continued laterally far from where they presently end; (4) *Principle of Cross-Cutting Relationships*, which tells that any geological body that cross-cut strata probably post-dates them; (5) and finally the *Principle of Inclusions*, if eroded chunks of one material are incorporated within another, then the eroded material must be older. These five principles are still used today to spatially order the different sedimentary-deposited strata. Although approximate, the addition of information from fossilized species (based on the Darwinian evolution) and radiometric ages of datable material (such as magmatic intrusions or metamorphic layers) help anchor these spatially ordered layers into age periods.

The discovery of sedimentary layers on Mars has brought scientists to use the same methodology described above. Mars has a simplified Geological Time Scale based on crater counting. Sedimentary stratified layers filling the bottom of Gale crater as observed by the Mars Science Laboratory mission and the Curiosity rover mission, or river-incised valleys crosscutting craters are a good example of applying the same principles of relative dating than on Earth. In both cases, deposited sediments and erosional features postdate the surface cratering, giving relative ages to those surface’s features.

Radiometric or absolute ages are based on the measurement of radioactive elements (parent elements) present in a rock or in its constituting minerals, and their decay products (daughter elements). Because the decay of radioactive elements is constant and unaffected by temperature, pressure, or oxygen fugacity conditions, an age can be obtained, assuming that the decay constant is known and that the mineral(s) containing both the parent and the daughter elements act as closed systems (no addition or loss of parent or daughter elements). Radiometric ages were available to date geological strata since the start of the twentieth century. In

1956, Clair Patterson at Caltech age-dated meteorites, which led to the first absolute age proposed for the Earth. Lunar samples brought to Earth by the first Apollo missions in the 1970s were age-dated with the Rb-Sr method. The *in situ* absolute dating of rocks directly on the surface of a planet, other than the Earth, is a very recent endeavor. In 2013, the team of Ken Farley at Caltech obtained a K-Ar age of 4.21 ± 0.35 Ga on a powder from the Gale crater (Mars) obtained using the drill of the Curiosity rover. The obtained age lacks precision, and it is likely a mixed age between that of older detrital (i.e., transported over a distance) sediments and younger authigenic (i.e., precipitated *in situ*) sediments. Yet, the age is compatible with that of 3.8–3.6 Ga obtained by relative dating for the Gale crater. Improvement in dating planetary distant surfaces will depend on the capacity of developing small portable automated laboratories able to separate minerals and by refining onboard analytical instrumentation. Yet, the potential of dating far planetary surfaces is enormous, even with the actual limitations.

Absorption

Definition

When a parallel, monochromatic beam of light traveling in some specific direction encounters a medium of finite extent, a certain amount of the flux will be absorbed and a certain amount will be scattered into other angles. The rate at which energy is taken out of the beam by absorption and scattering can be characterized in terms of coefficients with dimensions of area, which are known as cross sections. The term absorption cross section is often used to include both the portion due to scattering and that due to true absorption (loss of the photon into another form of energy, such as heat). For atmospheric gases, this total absorption cross section is defined by the Beer's law expression:

$$I = I_0 \exp(-\sigma n l)$$

where I_0 and I are the incident and transmitted light intensities, respectively, σ is the absorption cross section ($\text{cm}^2 \text{ molecule}^{-1}$), n is the molecular density, and l is the pathlength in cm.

Absorption Spectroscopy

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

In absorption ► [spectroscopy](#), the spectral features of interest appear in absorption with respect to a background continuous spectrum. In the interstellar medium, the background continuum may be supplied by a radiation source, such as a star, located behind the region of interest. The absorbing material may be either in the gas or the solid phase (e.g., interstellar dust or ices). Solid state features are much broader than atomic or molecular absorptions and are consequently more difficult to assign to a specific carrier. Much of the solar (Fraunhofer) spectrum is seen in absorption,

as the outer cooler layers of the solar atmosphere absorb radiation from the deeper photosphere. Spectral lines in planetary atmospheres are typically seen in absorption, against the continuous thermal spectrum from the planetary or satellite surface.

History

The first person to notice a number of dark features in the solar spectrum was the English chemist William Wollaston in 1802. This absorption spectrum was first systematically investigated by Joseph von Fraunhofer, starting in 1814, and the spectral features are now known as Fraunhofer lines.

Abundances

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Synonyms

[Fractional abundances](#)

Definition

Relative molecular abundances measure the chemical composition of an astronomical source or object. Such abundances can be either by mass or by number of molecules. For interstellar clouds, molecular abundances are typically presented as fractional abundances constructed from the measured molecular ► [column density](#), divided by the estimated H_2 column density of the source (Irvine et al. [1987](#)). For planetary or

satellite atmospheres, abundances are usually given in terms of the “volume mixing ratio”, the fractional number of molecules or atoms in a given volume relative to the total number of particles in the volume (de Pater and Lissauer [2001](#)).

Abundances of Elements

Nikos Prantzos
Institut d’Astrophysique de Paris, Paris, France

Keywords

Chemical composition · Nucleosynthesis · Nuclide

Definition

The relative amount (or fraction) of a given nuclide in a sample of matter is called the *abundance* of that nuclide. It can be expressed either in absolute terms (i.e., with respect to the total amount of matter in the sample) or in relative terms (with respect to the amount of some key element, e.g., the most abundant one, in the sample). Similarities and differences in the elemental and isotopic composition of ► [stars](#) and galaxies are key ingredients for understanding their origin and evolution.

Overview

The composition of remote objects (the Sun, ► [stars](#), interstellar gas, and galaxies) is determined through spectroscopy, which usually allows the determination of elemental abundances; in rare cases, particularly for interstellar clouds, some isotopic abundances may be determined in those objects. For Earth, lunar, and meteoritic samples, nuclear mass spectroscopy allows precise determination of most isotopic abundances; this is also the case for cosmic rays, albeit only for the most abundant nuclides at present. Hydrogen (H) being the most abundant element in the Universe, spectroscopists express the abundance of element i as the number ratio of its nuclei with respect to those of H: $n_i = N_i/N_H$, and they use a scale where $\log(N_H) = 12$. In the meteoritics community, the silicon scale of $\log(-N_{Si}) = 6$ is used. Theoreticians use the *mass fraction* $X_i = N_i A_i / \sum N_j A_j$, where A_j is the mass number of nuclide j ; obviously, $\sum X_i = 1$. Conversion of mass fractions to abundances by number

requires use of the quantity $Y_i = X_i / A_i$ called the *mole fraction* (notice that $\sum Y_i \neq 1$).

According to our current understanding, the material of the proto-solar nebula had a remarkably homogeneous composition, as a result of high temperatures (which caused the melting of nearly all the dust grains) and thorough mixing. This composition characterizes the present-day surface layers of the Sun, which remain unaffected by nuclear reactions occurring in the solar interior (with a few exceptions, e.g., the fragile D and Li). Furthermore, after various physicochemical effects are taken into account, it appears that the elemental composition of the Earth and meteorites matches extremely well with the solar photospheric composition. The composition of stars in the Milky Way presents both striking similarities and considerable differences with the solar composition. The universal predominance of H (90% by number, but $\sim 70\%$ by mass) and He (9% by number, but $\sim 25\%$ by mass) and the relative abundances of “metals” (to astronomers, elements heavier than He) is the most important similarity. On the other hand, the

Abundances of Elements, Fig. 1 Solar system abundances (by number) of the 92 chemical elements, in a logarithmic scale where $\log(N) = 6$ for Silicon. (From a compilation in Lodders [2003](#))

fraction of metals (*metallicity*, about 1.5% in the Sun) appears to vary considerably within the solar neighborhood (where the oldest stars have a metallicity of 0.1 solar), across the Milky Way disk (with young stars in the inner Galaxy having three times more metals than the Sun), or in the galactic halo (with stellar metallicities ranging from 0.1 to 0.00001 solar). These variations in composition reflect the history of “chemical evolution” of the Milky Way (Fig. 1).

Geochronology · Oldest rocks · Zircon

Samuel A. Bowring: deceased.

Synonyms

[Gneiss](#)

Definition

The Acasta Gneisses are the oldest rocks so far discovered on the surface of the Earth. They are exposed in northern Canada, north of Great Slave Lake, east of Great Bear Lake with the approximate position of 65° 10' N and 115° 30' W. They are granitic (*s.l.*) in composition and are interpreted to have formed, at least partly, from even older rocks that may be as old as 4.2 Ga.

Overview

The Acasta Gneisses are the oldest dated rocks on Earth. They are exposed in northwestern Canada (65° 10' N and 115° 30' W) along the western margin of the Archean Slave craton (>2.5 Ga), in the core of a north-trending fold in the foreland of the Wopmay orogen, a 2.02–1.84 Ga-old orogenic belt. The ages of Acasta Gneisses range from 4.03 to ca. 3.6 Ga, which group into three age clusters: 4.03–3.94 Ga, 3.74–3.72 Ga, and 3.66–3.58 Ga (Bowring et al. 1990; Bowring and Housh 1995). In each of these chronological groups, rock composition ranges from tonalite to granite through granodioritic. Since their genesis, these rocks have been deformed several times resulting in well-developed foliations (planar fabric present in metamorphic rocks and produced by reorientation of minerals). Lens-shaped boudins (cylinder-like structures making up a layer in a deformed rock) of serpentinized ultramafic rocks, up to several hundred meters long, occur throughout the gneisses. ca. 4.0–3.6-Ga-old metasedimentary rocks are lacking although sparse outcrops of locally tightly folded quartzite, iron formation, and pelite are found in the older gneisses. Many outcrops are cut by weakly deformed, ca. 3.6 Ga-old granitic dikes. During the 1.88 Ga Calderian orogeny to the west, sheets

of 1.9–2.5 Ga-old rocks were thrust over the western edge of the Slave craton, resulting in a set of north-trending folds and metamorphism of underlying Archean rocks. Ar-Ar biotite and U-Pb apatite dates record complex reheating during this event at ca. 1.77 Ga.

Most of the Acasta Gneiss protoliths have TTG (Tonalite-Trondhjemite-Granodiorite) composition, characterized by high light- and low heavy-rare earth element contents, which points to the involvement of residual garnet in their source (Martin 1987). On the other hand, several zircons crystals contain older xenocrystic cores with ages up to 4.2 Ga, which demonstrate that Hadean crust has been involved in the genesis of the Acasta protoliths through partial melting or assimilation (Iizuka et al. 2006, 2007).

Radiogenic isotope systematics in whole rocks (Sm-Nd) and zircon (Lu-Hf) are also consistent with the involvement of older ► [continental crust](#) (Guitreau et al. 2014; Reimink et al. 2018). The metamorphic imprint at ca 3.65 Ga, 3.6 Ga, and 3.4 Ga appears as zircon thin overgrowths.¹⁴² Nd signatures indicate that the oldest Acasta Gneisses were generated by partial melting of a hydrated, Hadean-age mafic crust at relatively shallow depths.

The formation and preservation of ► [continental crust](#) early in Earth's history is of broad interest to Earth scientists; indeed, the oldest continental crust provides information on the petrogenetic mechanisms as well as on the role played by water in generating granitic (*s.l.*) magmas 4 Ga ago. The ca. 4.0 Ga granitoids are very similar to those formed much later in Earth's history by plate-tectonic processes. No evidence of the late heavy bombardment is preserved in the Acasta Gneisses.

Accretion

Daniele L. Pinti

Geotop, Research Centre on the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Continental accretion](#); [Landmass accretion](#); [Planetary formation](#); [Plate accretion](#)

Definition

In planetary sciences, accretion is the process in which solid particles agglomerate together to form larger objects and eventually planets (*planetary accretion*). The initial conditions are a disc of gas and ca. 1% in mass of microscopic solid particles rotating around a young star. In geology, accretion is the process by which geological materials such as sediments, volcanic arcs, and pieces of continental crust, split from other continental plates, are added to a tectonic plate or to a landmass (*continental accretion*) participating in their growth with time.

Accretion Shock

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Generally, an accretion shock is a shock wave occurring at the surface of a compact object or dense region that is accreting matter supersonically from its environment. In the context of astrophysics, an accretion shock is normally understood to mean the shock wave present at the surface of the protosolar nebula or the corresponding nebula surrounding a ► [protostar](#), as it accretes interstellar matter from the surrounding molecular cloud.

Accretion, Stellar

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Definition

Stellar accretion refers to the inflow of ambient gas onto the surface of a star. During the process of star formation, accretion builds up the object to its final mass. The infalling gas is the interior portion of a ► [dense core](#), a small ► [molecular cloud](#) that collapses under the influence of its own gravity. The object being built up in this manner is a protostar and represents the first phase of stellar evolution. Some infalling gas impacts the protostar directly. Much of the gas, however, has sufficient angular momentum that it goes into orbit around the young star. The accreting gas thus creates a circumstellar disk. Matter spirals in through the disk onto the surface of the protostar. The remaining part of the disk eventually gives rise to planets.

Acetaldehyde

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Synonyms

[Acetic aldehyde](#); [Ethanal](#)

Definition

Acetaldehyde is an organic compound with the chemical formula CH_3CHO

It is the smallest aldehyde after formaldehyde. It is a colorless liquid at room temperature with an irritating odor. It can be obtained by the oxidation of ► [ethanol](#) or by the reduction of ► [acetic acid](#). When we drink alcohol, the ethanol is oxidized to acetaldehyde, by alcohol dehydrogenase, which is then oxidized to acetic acid by aldehyde dehydrogenase in the liver. It can be formed easily from gas mixtures containing methane by ultraviolet light and electric discharges, among others. It reacts with hydrogen cyanide and ammonia to give 2-aminopropionitrile, which gives ► [alanine](#) (amino acid) after hydrolysis. It has been detected in extracts from carbonaceous chondrites. Melting point: $-123.5\text{ }^{\circ}\text{C}$, boiling point: $-20.2\text{ }^{\circ}\text{C}$, density: 0.788 g cm^{-3} .

Acetamide

William M. Irvine
Department of Astronomy, University of
Massachusetts Amherst, Amherst, MA, USA

Keywords

Molecules · Interstellar

Synonyms

[Acetic acid amide](#); [Ethanamide](#)

Chemical Formula

CH_3CONH_2

Definition

Acetamide is an organic molecule with potential astrobiological significance, since it includes an amide bond, $-\text{NHCO}-$, which makes it potentially a marker of hydrolytic activity. Acetamide has been detected in the interstellar medium in the Galactic Center molecular cloud SgrB2, in carbonaceous chondrites (e.g., Halfen et al. 2011), and also apparently in the nucleus of comet 67P/Churyumov–Gerasimenko by the Philae lander as part of the Rosetta mission of the European Space Agency (Goesmann et al. 2015).

2-(Methylamino) Acetic Acid

- [Sarcosine](#)

Acetic Acid

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Synonyms

[Ethanoic acid](#)

Definition

Acetic acid is a ► [carboxylic acid](#) with the chemical formula CH₃COOH

It is a colorless liquid at room temperature with an irritating odor. Pure anhydrous acetic acid is sometimes called glacial acetic acid. It can be obtained by oxidation of ► [acetaldehyde](#), which occurs in human liver catalyzed by the enzyme aldehyde dehydrogenase, or by the hydrolysis of acetonitrile. It is easily formed in chemical

evolution experiments, e.g., it was found among the products of spark discharge experiment in a gas mixture of methane, ammonia, hydrogen, and water by S. L. Miller in 1953. It has been found in extracts from carbonaceous ► [chondrites](#) and has also been identified in ► [molecular clouds](#). Melting point: 16.6 °C, boiling point: 117.8 °C, density: 1.0492 g cm⁻³, acidity constant (p*K*_a): 4.76.

Acetone (CH₃COCH₃)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

[Propanone](#)

Definition

The organic compound acetone (CH₃COCH₃) is the simplest example of a ketone. Under standard

conditions, it is a colorless, flammable liquid. Acetone is naturally produced by normal metabolic processes in the human body. Since it is miscible with water, it serves as an important laboratory solvent. Rotational transitions in both the ground vibrational state and in the first excited torsional state have been detected by radio astronomers in ► [molecular clouds](#).

History

Although detection of acetone in a molecular cloud toward the center of our ► [Milky Way](#) galaxy was reported by radio astronomers in 1987, secure confirmation of its presence in interstellar clouds was not achieved until some 15 years later.

Cross-References

- [Milky Way](#)

Acetylene (C_2H_2)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

[Ethyne](#), [HCCH](#)

Definition

Acetylene is the simplest alkyne (hydrocarbons that have a triple bond between two carbon

atoms, with the formula C_nH_{2n-2}). Under standard conditions in the laboratory, it is a colorless but unstable gas. Because of its symmetry, linear of the form HCCH, it lacks a permanent electric dipole moment and hence has no allowed pure rotational transitions, making it undetectable at millimeter wavelengths. Astronomers have observed its vibrational transitions in the infrared, in both ► [molecular clouds](#) and in the envelopes of evolved stars. It is an important link in the chemistry of heavier carbon chain molecules and related species in these regions. Acetylene is also found as a minor component in the atmospheres of gas giants like the planet ► [Jupiter](#), in the atmosphere of Saturn's satellite ► [Titan](#), and in ► [comets](#).

History

Acetylene was discovered in 1836 by Edmund Davy and then rediscovered in 1860 by French chemist Marcellin Berthelot, who coined the name "acetylene." It was first observed in the interstellar medium by Lacy et al. (1989) and in ► [Comet Hyakutake](#) and ► [Comet Hale-Bopp](#) (Brooke et al. 1996).

Achiral

Robert Hazen

Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA

Synonyms

[Mirror symmetric](#)

Definition

The term "achiral" is applied to any object – in astrobiology most commonly a molecule, a two-dimensional crystal surface, or a three-dimensional crystal structure – that is invariant (i.e., superimposable) with its mirror image. Achiral objects possess a plane of symmetry, either a mirror or a glide plane symmetry operator. Common achiral objects include a soccer ball, a pencil, and the letter "X," in contrast with chiral objects such as a snail shell, your left hand, and the letter "R." Common achiral molecules are H_2O , CH_4 , and NH_3 in contrast with such chiral biomolecular species as alanine and ribose. In chemistry, achiral should not be confused with racemic, although in neither case is the optical rotation of polarized light affected.

Acid Hydrolysis

Mark Dörr

University of Southern Denmark, Odense M, Denmark

Definition

Hydrolysis (Greek: υδωρ [hydor] = “water” and λύσις [lýsis] = “solution”) is a chemical reaction

in which a compound is cleaved by water. If a proton-donating compound (Brønsted acid) catalyzes the reaction, it is called “acid hydrolysis.” Formally one part of the cleaved reaction product receives a proton (H^+), the other a hydroxyl (OH^-) moiety of a water molecule. Hydrolysis can also be catalyzed by a base. The reverse reaction is called a “condensation reaction.”

Acid Maceration

Emmanuelle J. Javaux

Palaeobiogeology-Palaeobotany-Palaeopalynology, Geology Department, Université de Liège, Liège, Belgium

Definition

Acid maceration is a technique used to extract organic-walled ► [microfossils](#) or kerogen from rock. A rock sample is cleaned to remove external contamination and crushed into small pieces. About 25 mg is macerated in chlorhydric acid solution (HCl) to remove carbonate minerals, rinsed with distilled water, and then macerated in fluorhydric acid solution (HF) to remove silicate minerals. A following step of boiling the macerate in hot HCl removes fluorides formed during the previous acid step. This protocol may vary according to the nature of the rock, of the fossils, and of their degree of preservation. After neutralization of the final macerate with distilled water, the residue is filtered on sieves of desired size fractions, then mounted on microscopic slides or kept in vials for other analyses.

Acidophile

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Keywords

Archaea · Chemolithoautotroph · Eukaryote · Iron cycle · Prokaryote · Sulfur cycle

Definition

Acidophiles are ► [microorganisms](#) that thrive under acidic conditions, usually at very low pH (<3). Natural niches where acidophiles can be found are volcanic areas (Yellowstone), hydrothermal sources, deep-sea vents, metal mining activities (Iron Mountain, Rio Tinto), or in the stomachs of animals. Acidophilic organisms can be found in the different domains of the tree of life (► [Archaea](#), Bacteria, and ► [Eukarya](#)).

Overview

The best characterized acidophiles belong mainly to Bacteria and Archaea domains (Madigan and Martinko 2005). These microorganisms normally are associated to sulfuric pools, acid mine drainage, or hydrothermal sources, that is, environments where sulfur compounds are present. The origin of extreme acidic conditions is related with the ► [oxidation](#) of reduced sulfur compounds which determines the strong relationship between acidophiles and sulfur chemistry. But also some eukaryotes as the green algae *Dunaliella acidophila* and the red algae *Cyanidium caldarium* (both organisms can live below pH 1.5) and some fungi are acidophiles. Surprisingly, eukaryotic microbes are the principal contributors of biomass in some low-pH environments as ► [Rio Tinto](#), a Spanish river which has a pH of around 2 and contains much higher concentrations

of heavy metals than are typically found in fresh waters (López-Archilla et al. 2001). Some interesting results from Rio Tinto are related with evolutionary distances between acidophilic species that occur in the river and their neutrophilic relatives. Authors reported some results that offer insight into adaptation to an extremely acidic environment. Adaptations associated with the transition from a neutral to an acidic environment must occur relatively rapidly when measured on evolutionary timescales (Amaral-Zettler et al. 2002). Authors detected clones from the Rio Tinto that are closely related to neutrophilic species such as *Chlamydomonas noctigama*, *Chlorella minutissima*, and *Colpidium campylum*. From microscopic observations, rotifers were also identified as inhabitants of Rio Tinto, as well as heliozoans and other types of amoeba.

Acidophiles belonging to different orders of the archaeal domain have been identified, such as Sulfolobales (a particular order in the Crenarchaeota branch) and some facultative anaerobic thermoacidophilic microorganisms as *Acidianus brierleyi* and *A. infernus* and other thermophilic as *Metallosphaera sedula*, all of them related with metal mobilization in natural environments and mining processes, Thermoplasmatales (order included in Euryarchaeota branch), and some others groups as nanoorganisms associated to Iron Mountain Mine and called ARMAN (Archaeal Richmond Mine Acidophilic Nanoorganisms). The ARMAN group is composed by three different lineages deeply branched in the Euryarchaeota subgroup.

Acidophiles belonging to the bacterial domain are the phylum Acidobacteria, the order Aciditobacillales of ► [Proteobacteria](#), the genus *Acidithiobacillus* and *Leptospirillum*, and some other related microorganisms as *Acetobacter aceti*, a bacterium that belongs to the *Acetobacter* genus of Proteobacteria that produces acetic acid (vinegar) from the oxidation of ethanol.

Studies of mechanisms used for adaptation at low pH by acidophiles reported interesting results about efficient apparatus for pumping protons out of the intracellular space as a way of maintaining

cytoplasm at or near neutral pH (Kelch et al. 2007). Therefore, intracellular proteins are not forced to develop acid stability through evolution. However, some acidophiles, as *Acetobacter aceti*, have an acidified cytoplasm. In the case of acidophiles with acidic cytoplasm, all proteins are forced to evolve acid stability. *Acetobacter* has become as a good model for studying acid stability mechanisms. Several authors have studied proteins adapted to low pH and revealed that in acid-stable proteins there is an overabundance of acidic residues which minimizes low-pH destabilization induced by a buildup of positive charge. The relocation of acid-sensitive salt bridges to regions with important functions in the unfolding process is a very specialized case of acid stability for some proteins of acidophiles. But some others mechanisms for protein stabilization in acid conditions have been reported.

Applications

Acidophiles have industrial applications as in biomining and bioremediation. Among the methods used for acid mine drainage treatment, there are several which involve also metal-immobilizing bacteria as a way for metal sequestering. An important biotechnological application of acidophiles is the process known as bioleaching for metal extraction and exploitation of extremely low-grade ores. Not only bacteria but also fungi have been used in related projects (Mohapatra et al. 2007; Botuyan et al. 1996). Projects include nickel extraction with *A. ferrooxidans* and *Aspergillus* sp. fungi (Mohapatra et al. 2007) and sulfur removal from coal with *Acidithiobacillus* sp. or naturally present population bacteria on fossil fuels as coal (Gómez et al. 1997).

Acritarch

Emmanuelle J. Javaux
Palaeobiogeology-Palaeobotany-
Palaeopalynology, Geology Department,
Université de Liège, Liège, Belgium

Keywords

Organic-walled microfossils

Definition

An acritarch is a microscopic organic-walled hollow vesicle with an unknown biological affinity. The term comes from two Greek words: “acritos” (unknown) and “arche” (origin). Acritarchs are found in marine sediments from most of the geological timescale, from the Archean to the present, but were more abundant and diversified in the Proterozoic and the Paleozoic. Their diversity decreased in the Mesozoic.

Overview

The term “acritarch” was coined by Evitt (1963) to define any organic-walled ► [microfossils](#) that cannot be assigned to a known biological group. The acritarchs form a polyphyletic artificial group that may represent many different types of organisms, from bacteria to unicellular (protists) or multicellular eukaryotes (e.g., fungi, algae, animal eggs). Their size ranges from a few microns to a few millimeters, although most are microscopic. They are classed into several artificial morphogroups based on the morphology and presence and type of ornamentation of the vesicle. Filamentous organic-walled microfossils of unknown biological affinities are not included among acritarchs. In the Paleozoic, most acritarchs are assumed to represent cysts of marine planktonic algae (phytoplankton). Acritarchs are very useful to date and correlate marine sedimentary rocks (biostratigraphy), especially in the late Proterozoic and the Paleozoic, to

Acritarch, Fig. 1 Two acritarchs from the Mesoproterozoic (1.65 Ga Ruyang Group, China). *Left*, a spiny acritarch (acanthomorph); *right*, a smooth-walled acritarch (sphaeromorph). (Photograph: E Javaux)

reconstruct paleoenvironments, and to assess the thermal maturity of the organic matter (paleothermometer) and their potential as a source of hydrocarbon. Moreover, the detailed study of acritarch morphology, wall ultrastructure, and microchemistry gives precious information on the early evolution of eukaryotes in the Precambrian.

The oldest acritarchs known so far have smooth walls (sphaeromorphs) and are preserved in 3.2 Ga fine-grained detritic rocks deposited in tidal shallow marine waters (Mesoarchean). The oldest ornamented acritarchs (with concentric striations) are 1.9 Ga and interpreted as probable eukaryotes. The oldest spiny acritarchs (acanthomorphs) are unambiguously eukaryotic and 1.65 Ga. Acritarchs can be preserved as flattened vesicles in fine-grained detritic sediments (shales, siltstones) or in three dimensions by permineralization (partial or complete replacement by minerals) in cherts or phosphorites. They are studied in thin sections or extracted from the rock by ► [acid maceration](#), depending on their state of preservation (Fig. 1).

Activated Nucleotide

Kunio Kawamura
Department of Human Environmental Studies,
Hiroshima Shudo University, Hiroshima, Japan

Keywords

Chemical evolution · Nucleotide ·
Oligonucleotide · RNA

Synonyms

Nucleoside 5'-monophosphorimidazolid

Definition

An activated nucleotide is a nucleoside 5'-monophosphate possessing a leaving group, such as imidazole, which provides sufficient energy to form higher oligonucleotides. The activation of nucleoside 5'-monophosphates by N-P bond formation between the phosphate group and a base (such as an amino acid or an imidazole) seems to be essential for the abiotic formation of RNA oligomers. In contrast, DNA oligomers are less readily formed from activated deoxynucleotides.

Overview

The synthesis of ► RNA molecules may have been an essential step for the emergence of lifelike systems on the primitive Earth. In modern organisms, polymerization of RNA monomers only proceeds because thermodynamics and kinetics allow for biochemical polymerization in organisms. In modern biology, nucleoside 5'-triphosphate monomers are used to form RNA polymers. This is thermodynamically favorable, since nucleoside 5'-triphosphates possess high-energy phosphate groups. These by themselves are rather kinetically slow to react in solution; however, their polymerization becomes kinetically favorable due to the involvement of biological catalysts, RNA polymerases. In addition, biological nucleotide polymerization is usually conducted on a DNA template; in the absence of an RNA polymerase or a template, the polymerization of 5'-triphosphate does not proceed.

RNA polymers are also formed in biology from nucleoside 5'-diphosphate in the presence of polynucleotide phosphorylase without a DNA template. This is an exception, although this does show that the polymerization of nucleoside 5'-diphosphates is also thermodynamically possible.

As mentioned above, the polymerization of nucleotide 5'-triphosphates does not proceed in the absence of an enzyme and a polynucleotide template. Since enzymes are fairly complicated biological catalysts, and since the first nucleic

acids must have predated the first nucleic acid templates, primitive pathways to form RNA polymers without an enzyme and a template molecule have been investigated under simulated Earth conditions. The activation of nucleoside 5'-monophosphates is essential thermodynamically, since the nucleoside 5'-monophosphate does not possess sufficient energy to form phosphodiester bonding. These monomers also have the experimental benefit of reacting quite rapidly under laboratory conditions. Furthermore, the activation should have occurred from plausible precursors under primitive Earth conditions. Investigations by Orgel and coworkers have shown that the nucleoside 5'-monophosphate monomers, that is, nucleoside 5'-monophosphoimidazolides and related compounds, can be considered as candidate primitive activated nucleotide monomers, as they can be formed under plausible primitive Earth conditions (Lohrmann and Orgel 1973; Orgel and Lohrmann 1974; Lohrmann 1977; Huang and Ferris 2006). RNA oligomers up to 50 nucleotide units can be formed from the activated nucleotide monomers in the presence of a metal ion catalyst, a clay mineral catalyst, or a polynucleotide template. In contrast, DNA oligomers do not form readily from the activated nucleotides.

Washington, DC, USA

Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Synonyms

E_a

Definition

In chemical kinetics, the activation energy (abbreviated E_a) is the energy barrier which must be overcome for a sufficient number of reactant molecules to acquire enough kinetic energy for a reaction to occur appreciably. The activation energy can generally be achieved by supplying energy, for example, in the form of heat, to the system or through the intervention of a catalyst. The Arrhenius equation gives the temperature dependence of the rate constant k : E_a is obtained from the slope of a plot of $\ln k$ versus $1/T$, where T is the absolute temperature in Kelvin. The activation energy is usually measured in kJ/mol.

E_a is related to the rate (k) via the equation

$$E_a = -RT \ln(k/A)$$

where A is a constant called the frequency or pre-exponential factor, usually given in units of s^{-1} , and R is the universal gas constant.

Active Asteroid

Gerhard Hahn

Asteroids and Comets, DLR, Institute of
Planetary Research, Berlin, Germany

Synonyms

Dual status objects; Mainbelt comet

Definition

Objects in typical asteroidal orbits, e.g., located in the main asteroid belt, showing typical cometary activity, such as tails or comae, either temporarily or sporadically. The possible origin of this “cometary” activity may either be intrinsically comet-like, e.g., outgassing, or triggered externally, e.g., by impact events, collisions, etc. Such objects are not confined to the asteroid belt, but exist also in the NEO population, and among Centaurs. A comprehensive recent review can be found in Jewitt (2012).

History

The first observation of such an object was the Centaur asteroid (2060) Chiron = 95P, which was found in 1988–1989 to show unusual brightening that could be related to comet-like activity exhibiting a coma. A member of the NEO group that was observed as both an asteroid and as a comet is (4015) Wilson-Harrington = 107P. Mainbelt asteroid (7968) Elst-Pizarro = 133P shows repeated activity, most likely caused by sublimation of water ice.

Most recent related finding is the detection of water vapor on dwarf planet Ceres = asteroid (1) Ceres.

Activity

Henderson James Cleaves
 Earth-Life Science Institute (ELSI), Tokyo
 Institute of Technology, Tokyo, Japan
 Blue Marble Space Institute of Science,
 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

In chemistry, the activity of a species is a measure of its effective concentration, as distinct from its concentration. This is, by convention, usually presented as a unitless value. Activity can be affected by factors such as pressure, temperature, and the presence of other solutes. The difference in value between concentration and activity is due to the fact that molecules in solution often display non-ideal behavior due to molecular interactions. In the gas phase, activity is called fugacity.

Activity, Magnetic

Thierry Montmerle
 Institut d'Astrophysique de Paris, Paris, France

Keywords

Magnetic fields, Chromosphere, Corona, and Flares · Dynamo effect · Doppler-Zeeman imaging · UV radiation, X-rays

Definition

Magnetic activity is a characteristic of low-mass stars, with the Sun as a prototype. Its most

spectacular observational manifestation is in the form of stellar flares that can be seen in the optical domain, UV, and X-rays. These flares correspond to the release of magnetic energy, itself temporarily built up as a result of movements of the outer layers of these stars, which are convective (“dynamo” effect). During flares, the stellar luminosity is enhanced by a factor which depends on the energy domain, but which is maximum in X-rays (amplification by a factor of up to 10 or more). The whole phenomenon typically lasts a few hours and may be described by a rapid heating phase (minutes to tens of minutes), followed by a long cooling phase (a few hours).

History

The Sun is the first known celestial X-ray source. It was discovered by rocket observations in 1949 by a group of physicists in New Mexico, USA (Friedmann et al. 1951). Since EUV photons and X-rays cannot penetrate the Earth’s atmosphere, studies continued using high-altitude balloons, and finally satellites (50 launched in the world between 1957 and 2021, including satellites hosting also other detectors, like EUV or gamma-rays). The first solar X-ray images were obtained on the *Skylab* space station (1973–1979), establishing the link between X-rays and magnetic fields. The Sun is now continuously monitored by satellites on various orbits, including heliosynchronous. Following the progress in solar X-ray imaging, the X-ray emission from individual stars was discovered by the *Einstein* satellite (1978–1981), already showing “solar-type activity” (flares), hence magnetic in origin. The largest X-ray telescopes, still in operation 22 years after their launch (NASA’s *Chandra* and ESA’s *XMM-Newton*) have detected hundreds of thousands of stars with evidence for magnetic activity.

Overview

Solar Activity

The prototype of a “magnetically active star” is the Sun, for which high-resolution images show,

Activity, Magnetic, Fig. 1 The Sun in visible light, during its ultraquiet period of Spring 2009. Note the two minuscule black “spots”: They are the silhouettes of the Space Shuttle servicing the International Space Station (photograph NASA/T. Legaut)

Activity, Magnetic, Fig. 2 The Sun in visible/EUV light, having regained its activity in early 2010. The hot gas is confined by closed magnetic loops in many places, in particular here at the limb (color-coded: bright regions are the hottest, $\sim 10^6$ K). There are also open magnetic field structures, which let the hot gas escape in the form of the solar wind. (*Solar Dynamics Observatory*, NASA)

at all wavelengths, numerous localized “active regions” (the largest ones seen as sunspots in the visible domain). The solar magnetic activity is best seen at “hot” temperatures (10^5 – 10^7 K), i.e., in the EUV and X-ray domains. The corresponding regions are, respectively, called the “chromosphere” and the “corona.” Magnetic activity is also seen in the visible domain, which corresponds to the “photosphere” (the surface of the Sun as we see it with the naked eye). A closer view shows that the solar surface is constantly in motion: This is due to the phenomenon of *convection*, which is the result of energy transport from the interior of the Sun. Figure 1 shows the optically visible Sun in its ultraquiet epoch of Spring 2009, and Fig. 2 shows for comparison the optical/EUV Sun, which regained activity a few months later. These structures evolve with time: on long timescales (days, weeks: starspots, prominences), but more spectacularly on timescales of hours (flares, such as the one seen on the solar limb of Fig. 2). Solar flares reveal material being heated in a few tens of minutes and confined by large magnetic loops; subsequently, the material cools, decays, and eventually flows back to the photosphere after a few hours. The magnetic field

is created via the so-called “dynamo effect,” resulting from the macroscopic movement of electrically charged convective gas. As shown on Fig. 3, the contrast between “active” regions and “quiet” regions is stronger at X-ray energies. This turns out to be a crucial factor for studying stellar magnetic activity.

Stellar Magnetic Activity

The so-called stellar “magnetic activity” is a characteristic of all “solar-type stars” (by extension from the Sun: relatively cool stars with temperatures between 3000 K and 10,000 K, and masses between ~ 0.1 Msol and ~ 2 Msol; for comparison, the surface temperature of the Sun is ~ 6000 K). These stars have convective outer layers and generate their own magnetic field by the dynamo effect like the Sun. The crucial observational difference between these stars and the Sun is that they cannot be resolved; in other words, they appear as points in any imaging device. However, one can reconstitute to some degree the stellar surfaces by using their *rotation*, which modulates the signal: Since active regions (such as spots) are

Activity, Magnetic, Fig. 3 The Sun in X-rays, as seen by the Japanese Hinode satellite. Active regions are again tightly linked with magnetic loops. Here the brightest regions reach a temperature of several $\sim 10^7$ K. (JAXA)

Activity, Magnetic, Fig. 4 Image reconstruction of the active regions and magnetic field topology of the young star SU Aur, observed via Zeeman-Doppler imaging. (@ Wikipedia: P. Petit, Observatoire Midi-Pyrénées)

cooler, hence darker than the surrounding surface, their emission is Doppler-shifted when the spots appear to move toward, then away from, the observer, as the star rotates. In favorable cases, it is possible to go one step further, by using the Zeeman effect. This is a physical phenomenon in which, under the influence of magnetic fields, specific spectral lines are slightly splitted into three components, sensitive to polarization, and which are also Doppler-shifted as a result of stellar rotation. Using sophisticated deconvolution methods, one can then reconstruct not only the location and size of active regions, but also the topology of their associated magnetic fields. Figure 4 shows such a reconstruction in the case of a young solar-type star.

A broader view of stellar magnetic activity is provided by X-rays. In particular, the generally large field-of-view of X-ray telescopes allows the simultaneous study of all the stars in the field, especially if they belong to a cluster. This is the case for young, premain sequence stars (“T Tauri” stars): As shown as an example on Fig. 5, over 2000 stars can be observed simultaneously in the Orion star formation region (associated with its famous nebula M42). Long exposures (several

days) reveal the occurrence of ubiquitous X-ray flares, most very similar to solar flares, and a few being of much longer duration and extreme temperatures (up to 10^8 K).

Basic Methodology

Solar and stellar magnetic activity are observed essentially from space. NASA’s solar satellite SDO (*Solar Dynamics Observatory*), launched in February 11, 2010, transmits high-resolution full-disk optical/EUV images at the unprecedented rate of 1 image per second (Fig. 2). Meanwhile, ESA/NASA’s SOHO (*Solar and Heliospheric Observatory*), launched in December 1995, will continue to provide data until 2025 on the Sun activity and solar wind in the same domain, covering in all almost three full solar magnetic cycles of 11 years. The Sun is also imaged in X-rays (Fig. 3), in particular by a series of Japanese-led satellites (*Yohkoh*; now *Hinode* since 2006), providing the best comparison set for stellar magnetic activity studies. Stars are observed using X-ray satellites (NASA’s *Chandra* and ESA’s *XMM-Newton*, both launched in 1999

Activity, Magnetic, Fig. 5 The Orion nebula seen in X-rays. *Left:* Near-IR image of the Orion Nebula cluster, which contains ~ 2000 stars (ESO/VLT/ISAAC). *Right:* X-ray image of the same cluster, obtained with the *Chandra* satellite (NASA). An excellent, one-to-one

correspondence holds between the stars visible on the left, and the point X-ray sources visible on the right. A long exposure of this region shows ubiquitous flares from all the low-mass stars. (From Montmerle et al., *Earth, Moon & Planets*, 98, 39–95, 2006)

and still in operation) that have both a large field of view (a fraction of a square degree) and high spatial resolution. In the case of *Chandra*, the spatial resolution is comparable with that of the best ground-based telescopes ($0.2''$ along the axis), allowing to resolve compact stellar clusters like those found in star-forming regions. In addition to imaging, X-ray satellites also have spectral capabilities, allowing to measure densities, temperatures and composition of the X-ray-emitting plasma, and their dependence with time (for instance, flares and associated coronal emission).

Key Research Findings

The vast majority of “solar-like stars” show evidence for magnetic activity, and observations show that X-rays are an excellent proxy to compare with solar magnetic activity. However, the level of activity is very different depending on stellar type. This level is generally measured by the ratio of the energy output in X-rays (the X-ray luminosity L_X), to the total energy output (the bolometric luminosity L_{bol}). For the Sun, $L_X/L_{\text{bol}} \sim 10^{-7}$, with an amplitude of a factor ~ 10 over magnetic cycles. In contrast, fully convective

stars like “emission-line,” late-type cool stars, and very young T Tauri stars have L_X/L_{bol} reaching $\sim 10^{-3}$. This limiting factor is due to “saturation,” i.e., when active regions cover essentially all the stellar surface, as opposed to 5% for the Sun. For the youngest T Tauri stars (ages less than a few Myr), the magnetic activity is altered by another phenomenon, which is the accretion of material from a circumstellar, protoplanetary disk, along large-scale magnetic field lines connecting the star and the disk. This phenomenon is seen as “soft” X-ray (< 1 keV) emission due to a shock when the accreted material falls onto the stellar surface, superimposed on the “hard” (> 1 keV) coronal emission.

Applications

For present-day human environment, the solar magnetic activity is strongly related to the notion of “space weather,” i.e., the interaction of the solar wind with the Earth’s magnetic field. For astrobiology, X-rays from the young Sun (and from young stars in general) may have had an important influence, via ionization of atoms and molecules, on early planetary atmospheres. More generally,

the study of solar and stellar magnetic activity is related to fundamental plasma physics: low-density plasmas in the corona and (in the case of young stars) interaction with a circumstellar disk; high-density plasmas in motion, leading to the generation of magnetic fields in outer convective zones (dynamo effect). Theoretical developments are now based on sophisticated numerical 3D simulations.

Future Directions

From an astronomical point of view, the similarities between solar and stellar magnetic activity allow two different approaches to the same problem, i.e., the origin of stellar magnetic fields: (i) considering the “Sun as a star,” where proximity allows detailed, localized studies; (ii) considering “stars as suns,” allowing statistical approaches on magnetic activity properties as a function of spectral type (mass, age, and evolutionary status) for thousands of stars, in particular for young stars at the stage of planet formation.

Adakite

Hervé Martin
Laboratoire Magmas et Volcans, Université
Clermont Auvergne, Aubière Cedex, France

Keywords

Adakite · Archean TTG · Hot subduction · Slab melting

Definition

Adakite is a volcanic rock of dacitic composition (dacite is a rock between intermediate andesite and felsic rhyolite and mainly composed of plagioclase, feldspar, and quartz) which emplaces in ► [subduction](#) zones. While most subduction-related magmas are generated by hydrous melting of the mantle wedge, adakites result from the melting of the subducting slab itself. Their geochemical composition is very similar to that of Archean ► [tonalite-trondhjemite-granodiorite](#) rocks or TTGs, of which they are modern analogues. This similarity supports the hypothesis that Archaean continental crust – dominated by TTG terranes – was generated in subduction-related environments.

Overview

Adakites are present-day volcanic rocks of dacitic composition, only little plutonic equivalents are known today (Bourgeois et al. [2016](#)). Martin ([1999](#)) showed that they are sodium-rich ($3.5\% \leq \text{Na}_2\text{O} \leq 7.5\%$) and relatively potassium-poor ($\text{K}_2\text{O} / \text{Na}_2\text{O} \sim 0.42$). Their Sr

Hervé Martin: deceased.

content is high ($\text{Sr} > 400 \text{ ppm}$, $\text{Sr}_{\text{average}} = 706 \text{ ppm}$), they have fractionated REE (► [Rare Earth Elements](#)) patterns ($(\text{La} / \text{Yb})_{\text{average}} = 20.4$) and typical low HREE contents ($\text{Yb}_{\text{average}} = 0.93 \text{ ppm}$).

Adakitic active volcanoes are only found in subduction zone environments, mainly along the circum-Pacific “Ring of Fire,” which is a belt of active arc volcanoes bordering the Pacific Ocean. They emplace exclusively where the subduction and/or the subducted slab are young ($< 30 \text{ Ma}$). Since pioneer works of Kay (1978), Rogers et al. (1985), and Martin (1986), it has been shown that under specific conditions (hot subduction), the subducted oceanic basalts can melt and give rise to acid and sodium-rich magmas, today known as adakite (Drummond and Defant 1990).

Martin (1999) proposed that adakites could represent the modern effusive equivalents of the Archean TTGs, proposition that was immediately challenged by Smithies (2000). However, in a more recent article, Martin et al. (2005) show that the term adakite in fact covers two families of magmas of different origins:

1. One rich in silica (HSA = High-Silica Adakites) is the product of melting of hydrated basalts in the garnet-stability domain; and whose chemical composition is very similar to that of Archean TTGs;
2. The other with low silica contents (LSA = Low-Silica Adakites) is generated by partial melting of a mantle peridotite previously metasomatized by magmas with HSA composition. LSAs are in no way an analogue of the Archean TTGs.

The very strong similarities that exist between modern HSA and TTGs attest that both have the same source and petrogenesis. Consequently, when Archean-like *Pressure–Temperature* conditions are exceptionally reached in modern subduction zones, Archean-like magmas are generated. This analogy strongly supports the hypothesis that Archean continental crust genesis took place within a subduction geodynamic environment.

Adaptation

Susanna Manrubia
Systems Biology Program, Centro Nacional de Biotecnología (CSIC), Madrid, Spain

Keywords

Ecosystem · Environmental change · Genetic change · Mutation · Phenotype · Selection

Definition

Adaptation is a dynamical process whereby populations become better suited to their habitat. It is promoted by environmental changes, be they abiotic (e.g., climatic change) or biotic (e.g., the appearance of a new trait in a predator or the extinction of a competitor ► [species](#)). Adaptation is the outcome of ► [natural selection](#) acting on heritable variation and leading to a change in the genetic makeup of a population. It may involve changes in any phenotypic trait, among others, in morphology, physiology, dispersal, defense and attack mechanisms, development and growth, reproduction, behavioral patterns, and ecological interactions.

Overview

Adaptation has been an ongoing process ever since the emergence of the first self-replicating molecules. Populations of replicating entities generate continuous variability chiefly due to ► [mutations](#) and (in the case of organisms) to the migration of ► [genes](#) and other mobile genomic sequences. Adaptation is a gradual process that occurs over many generations as the offspring (i.e., the genes) of individuals best suited to the current habitat become increasingly abundant. Under environmental changes, species can react in three different ways. In case of slow change, they (1) perform habitat tracking if the change is exogenous (i.e., the population shifts with the ► [environment](#) to maintain the characteristics of its habitat) or (2) undergo genetic change. Only in the latter case are they truly adapting. If changes are too sudden, species cannot adapt and (3) become extinct. Even if the abiotic environment remains constant, the steady generation of mutants within a population compels related species to change. The appearance of teeth and claws in predators forces a simultaneous improvement in defense organs (as skeletons) to escape extinction. This sustained competition is called the Red Queen effect (Van Valen [1973](#); Stenseth and Maynard Smith [1984](#)).

Many adaptive changes in the history of life are gradual and involve a significant number of sequential modifications, as the evolution of tetrapod limbs from the fins of precursor fish. Some changes (the invention of lungs, of vascular systems in terrestrial plants, or of organs for flight) permitted organisms to colonize new ecological niches (Gould [1993](#)). Certain major transitions in evolution (Maynard Smith and Szathmáry [1995](#)) are probably not the result of adaptation, but of contingency. Such might be the case for the appearance of eukaryotic cells or of multicellular organisms.

Since natural selection acts on the phenotype as a whole, it is impossible to simultaneously improve all its traits in the same degree (Mayr [1982](#)). Also, traits that were once the result of adaptation may turn to be disadvantageous when the habitat changes. Hereditary hemochromatosis causes an excessive absorption of iron that accumulates in human body tissues. This disease is more common among Europeans: it protects against bacterial infections and probably became frequent at the time of the Black Death (Moalem and Prince [2006](#)). This is an example of the many currently nonadaptive traits that were permitted to thrive at some point of time in the history of a species.

Adaptive Optics

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Adaptive optics is a technique, used while performing visible or near-infrared imaging from a ground-based telescope, that improves the image quality that is otherwise degraded by the atmospheric turbulence. The wave-front distortions, measured on the studied object or a nearby star, are compensated by deforming a small, thin mirror at a speed higher than turbulence (1 kHz typically) (Fig. 1). The deformable mirror is conjugated to the pupil of the telescope. The use of this technique is mandatory in any method, such as coronagraphy, that aims at a direct imaging of exoplanets.

In the mid of the last decade, adaptive optics systems especially optimized for direct detection of circumstellar disks and exoplanets were installed on several very large telescopes: SPHERE on the VLT, GPI on Gemini South, and SCExAO on SUBARU. Notably they feature what is called extreme adaptive optics (XAO) that allows to reach an effective angular resolution q (angular size of the smallest detail on an image) practically equal to the theoretical limit $q = \lambda/D$ where λ is the wavelength and D the diameter of the telescope.

Adaptive optics should not be confused with active optics that corresponds to corrections

Adaptive Optics, Fig. 1 Cartoon describing the principle of adaptive optics: The wave front deformed by atmospheric turbulence is corrected thanks to a deformable mirror that produces an inverse deformation several hundred times per second, after a device called a wave-front sensor has measured the residual distortion. A real-time computer is used to analyze the residuals and to define the proper surface to give to the mirror. The final improved image is obtained on a camera

applied to the large primary telescope mirror, deformed under gravity, at a much lower frequency (0.1 Hz).

Adiabatic Processes

Guillaume Chaverot

Observatory of Geneva, University of Geneva,
CH-1290 Versoix, Switzerland

Definition

A thermodynamic process is called *adiabatic* if there is no heat exchange between the considered air or fluid parcel and its surroundings. Consequently, temperature changes are induced by a change in pressure. This process is a key point to determine the temperature gradient of planetary atmospheres and also of oceans.

In planetary atmospheres, an air parcel drifted upward cools and expands due to the decrease in atmospheric pressure. The rate at which the temperature falls is quantified by the *adiabatic lapse rate* (Pierrehumbert 2010; Wallace and Hobbs 2006). If the partial pressure of the condensable gas is below the *saturation pressure*, the process is called *dry adiabatic*, and its lapse rate is $-dT/dz = g/c_p$ where g is gravity acceleration and c_p the heat capacity of the gas. Indicative lapse rate values of different planets are given in Table 1.

When the pressure reaches the saturation pressure, the process is called *moist adiabatic*, and the addition of *latent heat*, by condensation or evaporation of the gas, leads to define a *moist adiabatic lapse rate* different from that of dry air. This is true whatever the considered condensable gas.

Adiabatic processes also play a role to determine the thermal structure of oceans (Stewart 2008) (even on icy moons), but the adiabatic lapse rate depends as well on other physical processes (e.g., salinity).

Adiabatic processes are often considered isentropic, thus reversible, i.e., the entropy remains unchanged. In other words, the system evolves slowly enough to reach the thermodynamic equilibrium at all times.

Although there are thermal exchanges at the surface interface (e.g., atmosphere/ocean

Adiabatic Processes, Table 1 Estimation of the dry adiabatic lapse rate of the atmosphere of different planets. The given value is computed at surface pressure and temperature

	Dry adiabatic lapse rate (K/km)
Earth	9.8 (Zurek 2017)
Venus	10 (Limaye et al. 2018)
Mars	5.0 (Zurek 2017)
Titan	1.3 (McKay et al. 1997)

interface), the surface temperature of a planet is mainly determined through adiabatic processes in planetary atmospheres (and oceans); therefore, they are a key point to study planetary habitability.

Aerobic Mesophilic Bacterial Spore

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Aerobe

Felipe Gomez
Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

Aerobes are organisms that can tolerate or require the presence of (strict aerobe in this case) oxygen. Oxygen is an extremely strong oxidant and produces very reactive radicals, which react with amino acids or nucleic acids inactivating the functional sites of enzymes or producing lethal mutations. Practically, all animals are aerobes; most fungi and many prokaryotes can survive in the presence of oxygen. To do so, aerobic organisms require the presence of detoxification activities, like catalases and peroxidases. Among aerobes there are different kinds of organisms: obligate aerobes, which require oxygen for growth and use oxygen as final ► [electron acceptor](#) in the ► [respiration](#) process; facultative aerobes, which can use oxygen or not, to obtain energy; micro-aerophiles, which require low levels of oxygen; and aerotolerants, which are not affected by the presence of oxygen.

Definition

The term “spore” as used in planetary protection is a shorthand form for “bacterial endospore,” which is a resistant dormant configuration produced by some ► [microorganisms](#) (principally Gram-positive bacteria) as a response to environmental stressors. Microorganisms are characterized as “aerobic” based on their ability to grow while exposed to oxygen, while “mesophilic” is descriptive for microorganisms that grow (in a lab on nutrient-rich media) at temperatures comfortable for humans (between 15 °C and 40 °C). Outside these preferred conditions (in the absence of oxygen, nutrients, or on exposure to temperature extremes), spore-forming organisms may form spores. In the spore configuration, these bacteria are capable of surviving extreme environmental conditions in dormancy, and then repopulating when reintroduced into a more hospitable environment. This aerobic mesophilic bacterial spore type is commonly used in ► [planetary protection](#) as a reference microorganism for the qualification of ► [bioburden](#) reduction processes, and quantitation of such spores on and in spacecraft is used as a proxy indicator for the cleanliness of spacecraft components and systems.

Biology, of the atmosphere · Microorganisms,
in the atmosphere · Pollen · Spores

Definition

Aerobiology is the study of the occurrence, movement, and dispersal of living or once-living material through the atmosphere.

Overview

The atmosphere presents a series of challenges for life, from radiation to desiccation. The absolute amount of solar radiation and the proportional contribution of ultraviolet B and ultraviolet C radiation increase with altitude, both of which are particularly hazardous to biomolecules. The low temperature and pressure at 29 km above the surface of the Earth are similar to those on Mars and create problems due to freezing and desiccation. Finally, the lack of nutrient availability in the atmosphere creates an additional challenge for life.

The survival of airborne microbes should not be confused with growth and division while airborne. In fact, one of the critical questions that has yet to be answered unequivocally is “do microbes metabolize and divide while airborne?” If they do, then the atmosphere may be considered a true habitat rather than just a place where they are transient interlopers. Although there are studies that suggest that airborne microbes have the potential to metabolize and divide in the atmosphere, these studies are inconclusive.

Given the hostility of the environment, Earth’s atmosphere just above the surface contains a variety of airborne microorganisms that are thought to originate from the soil, lakes, oceans, animals, plants, as well as any process causing aerosols or dust. The numbers of viable airborne microbes recovered from the atmosphere vary seasonally with the highest numbers obtained during the summer and fall and the lowest in the winter. The distances that airborne organisms may travel range from a few kilometers to thousands of kilometers. There is a statistically significant positive correlation between the total number of viable bacteria isolated from urban air and the concentration of suspended particulate matter in the air. The organisms may be protected from drying by adsorbed water on the surfaces of these suspended particles.

Studies of the biology of the upper troposphere and lower stratosphere (5–20 km) date back to the late 1800s using balloons. But these studies are few in number and not well controlled. The organisms collected included fungi and spore-forming bacteria.

Later studies reported a larger variety of nonspore-forming microbes, especially a variety of pigmented bacteria. However, the composition and prevalence of microorganisms in the middle to upper troposphere (8–15 km altitude) and their role in aerosol–cloud precipitation interactions are unresolved. Using meteorological rockets, fungi and pigmented bacteria have been isolated from as high as 77 km, the highest altitude from which microbes have been isolated. These studies, however, all used culturing methods to determine microbial counts. It has been estimated that those methods allow studying only between 0.1% and 10% of the total microbial flora in any given environment. Therefore, it is speculated that a number of microbes may exist in the upper atmosphere that we do not have the ability to culture and go unnoticed and uncultured. More recently, however, studies using molecular microbiology techniques, microscopy, and conventional culturing have shown that bacterial cells outnumber fungal cells in the upper troposphere.

Aerogel

Makoto Tabata

Department of Physics, Graduate School of Science, Chiba University, Chiba, Japan

Definition

An aerogel is a non-fluid colloidal system of a microporous (or mesoporous) solid in which pores are filled with a gas. It is usually used to indicate a silica aerogel. In this case, a mesoporous three-dimensional network is composed of nanoscale silicon dioxide clusters and the open pores are filled with air. Silica aerogels are optically transparent and are one of the most lightweight forms of condensed materials. The bulk density of aerogels can be controlled during the fabrication process. Low-density silica aerogels are often used to capture mostly intact cosmic dust in space.

History

Aerogels including silica-based aerogels were first created by Kistler (1931). Based on IUPAC Recommendations, an aerogel is defined as a “gel comprised of a microporous solid in which the dispersed phase is a gas” (Alemán et al. 2007). Of the aerogel family, silica aerogel (Fig. 1) is the most suitable material for capturing hypervelocity (km/s) cosmic dust grains while maintaining their chemical and structural properties due to its low-density characteristics. While decelerating, the dust particle forms impact cavities (referred to as a “track”) and is trapped inside the aerogel. The

Aerogel, Fig. 1 Hydrophobic 30 mg/cm³ silica aerogel with a dimension of 9 cm × 9 cm × 2 cm fabricated at Chiba University. Shorter wavelength visible light (blue) is strongly scattered by the aerogel structure of tens of nanometers (Rayleigh scattering)

optical transparency of the silica aerogel allows the impact track and the captured particles to be identified under optical/digital microscopes. The aerogel is stable in space, though the pore air is ejected into the vacuum. The use of silica aerogels as a cosmic dust collection media have been summarized by Tsou (1995) and reviewed by Burchell et al. (2006). In addition to silica aerogels, titanium-doped alumina–silica (Al₂O₃–SiO₂) hybrid aerogels have been suggested by Domínguez et al. (2004) to estimate the dust impact velocity using a fluorescent impact cavity imaging technique. Non-silica aerogels have also been studied by Jones (2010). Extended applications of aerogels in space exploration, including their use as thermal insulators, have been explained by Jones (2006).

To fabricate a silica aerogel, a wet silica gel is first synthesized via a sol–gel polymerization method involving the hydrolysis and condensation of a silica precursor. After aging, surface hydrophobic modification (optional) and solvent exchange are conducted. Finally, the wet gel is rendered to an aerogel by drying it using a supercritical extraction method, followed by baking at high temperature for purification (optional). More specifically, a two-step method is generally used in wet gel synthesis: a partially hydrolyzed, partially condensed silica precursor (silica oil) is produced, and then, a wet gel is synthesized

from the silica oil to obtain a highly transparent, low-density aerogel (Tillotson and Hrubesh 1992). The first step to obtain the silica oil can be omitted by using an industrial silica precursor chemical (one-pot sol–gel synthesis) as reported by Adachi et al. (1995). The aerogel density can be controlled by adjusting the volume ratio of the silica precursor and diluent solvents in the sol–gel process. Organic solvents (e.g., ethanol) or liquefied carbon dioxide are used as the supercritical fluid in the high- and low-temperature drying process, respectively. To preserve the hydrophobic groups on the surfaces of silica clusters, surface-modified aerogels cannot be baked.

The application of silica aerogels as intact cosmic dust collection media was first recognized by Tsou et al. (1988). The performance of aerogels in laboratory experiments to capture particles traveling at hypervelocity was investigated using projectile accelerators prior to space missions. Then, the aerogels were first used in two independent missions in low-Earth orbits around the same time. One was aboard a NASA space shuttle in 1992 (Tsou et al. 1993). The 9-day mission was equipped with 21 aerogel tiles with active dimensions of 9 cm × 9 cm × 1 cm and a density of 20 mg/cm³. Four hypervelocity particles captured in the aerogels were identified. The second was aboard the EURECA free-flying spacecraft of the European Space Agency (ESA) in 1992–1993 (Brownlee et al. 1994). Four 50 mg/cm³ aerogel collector modules with dimensions of 10 cm × 10 cm were exposed to space for 11 months. A total of 12 hypervelocity impact cavities were determined to have formed in the aerogels.

The first use of aerogel capture media in deep space was completed by the NASA mission Stardust, which was designed to bring the first extraterrestrial material samples back to Earth from a known planetary body (comet 81P/Wild 2) other than the Moon (Tsou et al. 2003). The Stardust spacecraft was launched in 1999, encountered the comet in 2004, and successfully returned thousands of dust particles to Earth in 2006 (Brownlee et al. 2006). For this mission, an aerogel block with a gradient density profile (ranging from 10 mg/cm³ to 50 mg/cm³) along

the 3-cm thickness direction was developed at JPL (Jones 2007). The Wild 2 sample collector was comprised of 132 gradient density, hydrophilic aerogel blocks with dimensions of 4 cm × 2 cm, which were manufactured via the two-step sol–gel method and the high-temperature supercritical drying method. The spacecraft was also equipped with an interstellar dust collector comprised of gradient density (ranging from 10 mg/cm³ to 20 mg/cm³) aerogel blocks with a thickness of 1 cm. Westphal et al. (2014) investigated seven candidate dust particles captured by the collector in the cruising phase that had an interstellar origin.

The most recent aerogel collection media was applied in a JAXA astrobiology mission, Tanpopo, which was conducted aboard the International Space Station (ISS) from 2015 to 2019. One of the primary objectives of this multifaceted experiment is to return dust possibly containing terrestrial microbes and interplanetary dust containing extraterrestrial organic compounds from low-Earth orbit to ground laboratories. For this mission, a double-layer aerogel tile with densities of 10 mg/cm³ and 30 mg/cm³ was developed at Chiba University, Chiba, Japan (Tabata et al. 2016). A total of 36 hydrophobic aerogel tiles with dimensions of 9 cm × 9 cm × ~2 cm were fabricated using the one-pot sol–gel method and the low-temperature supercritical drying method, and were launched for three annual experiments. All the aerogel tiles were annually returned to the ground by 2019, and dozens of hypervelocity impact tracks were found in the aerogels used in each year's experiment. The Tanpopo2 mission was continuously conducted aboard the ISS from 2019 to 2020.

Synonyms

[Atmospheric dusts](#); [Atmospheric particles](#); [Haze particles](#)

Definition

Aerosols are small liquid or solid particles in suspension in a gas. Solid smoke particles from the burning of vegetation, dust formed by wind erosion of soil, or liquid droplets produced by the ocean waves are examples of aerosols.

Aerosols are present in many planetary environments, for example, in the atmospheres of Mars, the giant planets, and ► [Titan](#), and they were probably present in the primitive atmosphere of the Earth, much as they are presently. Atmospheric aerosols can play an important role in

climate, producing an antigreenhouse effect, like the haze in Titan's atmosphere. Atmospheric photochemistry in several extraterrestrial environments, like Titan, produces organic aerosols which are similar to laboratory-synthesized ► [tholins](#), which can produce a complex set of prebiotic chemicals when reacted with water.

Affinity Chromatography

Mark Dörr
University of Southern Denmark, Odense M,
Denmark

Definition

Affinity ► [chromatography](#) is a (bio-) chemical separation method based on highly specific molecular interactions (affinity) such as between antigens and antibodies, ► [enzymes](#) and ► [substrates](#), or receptors and ligands. The stationary phase is commonly composed of beads of a gel (e.g., agarose gel) with a covalently bound ligand (e.g., an ► [antibody](#)). Affinity chromatography is one of the most powerful separation methods, as it combines the size fractionation capability of gel permeation chromatography with specific, reversible interactions of molecules.

History

The method was introduced by Cuatrecasas, Wilchek, and Anfinsen in 1968 (Cuatrecasas et al. 1968). Pedro Cuatrecasas and Meir Wilchek were jointly rewarded the Wolf Prize in Medicine 1987 for this discovery.

Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Synonyms

[Association constant](#); [Binding constant](#)

Definition

In chemistry and biochemistry, the affinity constant is the reciprocal of the dissociation constant, where both are equilibrium constants describing the strength of binding between a catalyst such as

an ► [enzyme](#) or ► [ribozyme](#) and its ► [substrate](#). A K_m value is a specific example of an affinity constant in enzymatic reactions. For example, the equilibrium for the formation of an enzyme-substrate (ES) complex between an enzyme (E) and a substrate (S),

can be represented as

$$K_m = \frac{|E_x S_y|}{[E]^x [S]^y} \quad (2)$$

where $[E]$, $[S]$, and $[ES]$ are the concentrations of enzyme, substrate, and the enzyme-substrate complex, respectively, and x and y represent their stoichiometric coefficients.

The affinity constant, also known as the Michaelis constant, has units of per molar (M^{-1}) or l/mole. Affinity constants can vary significantly with solution conditions (e.g., temperature, pH, and ionic strength).

This equilibrium is also the ratio of the rate of association (k_{ass}) and rate of dissociation (k_{diss}). Two different enzyme-substrate complexes may have the same affinity constants, but one could have a high k_{ass} and k_{diss} , while the other may have a low k_{ass} and k_{diss} .

Akilia

Minik T. Rosing
Nordic Center for Earth's Evolution, Natural History Museum of Denmark, University of Copenhagen, Copenhagen, Denmark

Definition

Akilia is the name of a small island (~2.3 km by 1.4 km) south of the town of Nuuk on the SW coast of Greenland (63.933°N, 51.667°W). The Akilia sequence of rocks has its name from this island, but they occur throughout the Eoarchean of West Greenland. The Akilia sequence consists mainly of granitic gneiss and includes some of the

oldest rocks on Earth. The largest member of this group of rocks is the ca. 3.8 Ga-old ► [Isua supracrustal belt](#) composed of metamorphosed pillow basalts, clastic, and chemical sediments that constitute the oldest known supracrustal sequence. Fractionated C, N, and S isotopic compositions of materials of probable sedimentary origin are thought to be biogenic and to provide the oldest record of life on Earth.

Overview

Ibn Tufayl's (Abubacer; d. 1185) main engagement with planetary theories was centered on his rejection of Ptolemaic eccentrics and epicycles as they contradicted the basic principles of Aristotelian physics. Ptolemy's eccentrics and epicycles implied two main violations of the classical principles of natural philosophy. On one hand, the eccentric meant that planets moved around a center different from the Earth. On the other hand, epicycles meant that planets moved west to east in their epicycles while moving east to west around the eccentric, therefore introducing double movement, which contradicted the single simple movement explained in works of natural philosophy.

While Ptolemy's model came close to solving the observational variation in movement, it violated significant principles of Aristotelian physics. Objecting to the Ptolemaic model required the production of different geometrical solutions that would allow for singular movement around the Earth and would explain the observations. Ibn Tufayl claimed to have arrived at a solution and promised to write it in a separate book but apparently never had the time to do so. Yet, Ibn Tufayl's student, al-Bitrūjī, credited his master by providing the basis for the former's solution.

Ibn Tufayl's objections had their roots in the works of Ibn Sīnā, who inspired much of Ibn Tufayl's works, including his most famous novella "Philosophus Autodidactus." Ibn Sīnā also rejected Ptolemy's model and claimed to have arrived at a solution, but after much effort he decided not to share it with any of his students and not to write it. Ibn Sīnā's student, al-Juzjānī, composed a solution for this problem in a letter addressed to his master. However, Juzjānī's solution was not sufficient.

Ibn Tufayl's more prominent student, Ibn Rushd (Averroes; d. 1198), wrote an epitome to Ptolemy's *Almagest* and acquired much of his fame because of his detailed commentaries on Aristotle. In his commentaries on Aristotle's metaphysics and *De Caelo*, Ibn Rushd criticized the Ptolemaic model and considered it to be unnatural. He explained that Aristotle and the ancients had arrived at perfect solutions for the celestial movement that escaped Ptolemy and that these solutions should be rediscovered. While he claimed to have worked on these solutions in his youth, Ibn Rushd left the task unfinished to his successors.

Ibn Tufayl's other student, al-Bitrūjī (d. 1204), who seemed to have worked entirely independently from Ibn Rushd without either of the two being aware of the other, was a more proficient astronomer and produced a model in which he attempted to address his master's objections. Bitrūjī maintained a homocentric universe in correspondence with natural philosophy, eliminating eccentrics and epicycles; he developed the notion

of rotating poles that was mentioned by Aristotle in *De Caelo*, even wondering why Ptolemy did not propose such a solution. Both Ibn Rushd and al-Bitrūjī accepted this polar movement, which was developed by Theon of Alexandria into spiral movement.

In addition to such cosmological discussions, the Toledan Tables, predicting the positions of the Sun, Moon, and planets, represented a more important contribution of Andalusian astronomers in fields of practical and computational astronomy. About a dozen astronomers in Toledo, the most prominent of whom was the astronomer and instrument-maker al-Zarqālī (Arzachel; d. 1087), and which included both Muslims and Jews, undertook different mathematical and astronomic calculations that resulted most prominently in the tables. Al-Zarqālī had an important theoretical contribution in relation to trepidation (a medieval theory related to the precession of the equinoxes), and he also improved Ptolemy's calculations of the length of the Mediterranean.

Keywords

Islam · Islamic astronomy · Avicenna ·
Medieval · India · Zij · Astrology · Calendar ·
Chronology

Overview

Abū Rayḥān al-Bīrūnī (d. 1048) was a Persian scholar of mathematics, astronomy, astrology, and geography, among other disciplines. Although he changed patrons frequently, he produced his most important works in the Ghaznavid court.

Educated in the dominant Greco-Islamic scholarship, Bīrūnī was interested in comparing different scientific traditions. His “Chronology of Ancient Nations” was a detailed exposition of calendars and chronologies used by different nations, including Arabs, Greeks, Persians, Jews, and Syriacs, among others. The *Chronology* was unprecedented in its comparative approach and its careful examination of different chronological systems. It also included detailed descriptions of these nations’ different religious feasts.

While accompanying the Ghaznavid sultan Maḥmūd (r. 998–1002) in India, Bīrūnī came in contact with Indian scholars and composed a significant volume where he addressed Indian religious beliefs and rituals, Indian sciences including astronomy and cosmology, and Indian chronology and calendars, which were missing from his *Chronology*. Bīrūnī’s work was the first to discuss “foreign” nations and histories in non-polemical fashion with the stated goal of understanding different scientific and belief traditions. His work in India included transmitting Ptolemy’s *Almagest* and other books of Greco-Islamic sciences to

Indian scholars. Bīrūnī’s comparative view was based on his stated belief that sciences are universal and they speak to universal laws of nature, only in different languages and using different models. Comparison of scientific theories, and of calendars and chronologies, was meant to explain the different approaches to a single universal truth.

Bīrūnī’s most influential text in the Islamic context was his *al-Qānūn al-Mas‘ūdī* (The Mas‘udic Canon), an 11-volume book in which he developed algebraic solutions of third-degree equations and distinguished between the motions of precession and the solar apogee. While the Canon was primarily based on Ptolemy’s *Almagest*, it was also an attempt at incorporating elements of Indian and Persian astronomy in the dominant Greco-Islamic tradition. Bīrūnī was aware of some difficulties in the Ptolemaic planetary theory. However, contrary to his contemporaries, Bīrūnī’s objections did not only stem from Ptolemaic violations of the principles of classical natural philosophy, as Avicenna’s (d. 1037) objections were, but were based on contradictions between the Ptolemaic system and Bīrūnī’s own observations. Bīrūnī’s correspondence with Avicenna showed some of Bīrūnī’s skepticism and doubts on Aristotelian natural philosophy.

While working as a court astrologer, Bīrūnī composed his *Tafhīm* on astrology, which he started with lengthy discussions of geometry and astronomy, with one quarter of the book for the actual discussion of judicial astrology. He argued that a well-trained astrologer, worthy of the name, must be proficient in all these sciences. As part of his systematic observations, Bīrūnī was interested in astronomical instruments – he wrote five books on instruments, including a lengthy one on the astrolabe. He also described a coordinated viewing of the lunar eclipse on 24 May 997 with Abu al-Wafa’ al-Buzjani (d. 998 CE) – from Khwarazm and from Baghdad – to better calculate coordinates of major Islamic cities. Some of Bīrūnī’s minor works discuss astronomical-mathematical concepts such as chords (Istikhraj al-awtār),

“shadows” or tangents (Ifrād al-maqāl), and planetary transits (Tamhīd al-mustaḡarr).

al-Tūsī, Nasir al-Dīn

Ahmed Ragab¹ and Allyssa Metzger²

¹Harvard Divinity School, Cambridge, MA, USA

²Harvard University, Cambridge, MA, USA

Keywords

Islam · Islamic astronomy · Maragha · Medieval · Mongol · Zij · Observatory · Tusi couple · Avicenna

Overview

Nasir al-Dīn Tūsī (d. 1274) was a Persian scholar of mathematics, astronomy, philosophy, and theology; he was considered by many “the Third

Teacher” after Aristotle and al-Farabi (d. 950). Tūsī’s most renowned activities took place in the Maragha Observatory in what is now Iran, where he led a group of scholars including Chinese astronomers in different investigations and activities. It has been suggested that Tūsī’s criticisms of Ptolemaic astronomy influenced Copernicus’ rejection of equants in his *De Revolutionibus* (1543).

Tūsī studied mathematics, medicine, and Avicennan philosophy at Nishapur, then jurisprudence, mathematics, and astronomy in Iraq. In 1233, he entered the service of the Shiite Ismaili emir, Ibn Abī Maṣṣūr, for whom he dedicated his work on ethics (*Akhlaqī Naṣiri*). He spent time in the Nizari strongholds of Alamut and Maymundiz, where he had access to their libraries and produced a number of his known works. In 1255, he was sent by the lord of Alamut to negotiate with Hūlegū Khan (r. 1256–1265), who led the Mongol westward advances. He remained in Hūlegū’s service, which may have been put him in charge of Muslim endowments (*waqfs*) or other important financial institutions. Hūlegū patronized Tūsī’s works and allowed him to start the construction of the Maragha Observatory in 1259. Maragha became a destination for many scholars who benefitted from Mongol patronage and from the impressive library that was culled from conquered libraries in Mesopotamia, Baghdad, and Syria. Tūsī and his colleagues at Maragha completed a *zīj* (table of parameters for calculating the positions of the Sun, Moon, and planets; the Ilkhanid *Zīj*) around 1270 under Hūlegū’s successor, Abaqa Khan (r. 1265–1282). The *zīj* might have been one of the more practical tasks of the observatory.

Tūsī is best known for the Tusi couple – a mathematical device that transforms circular to linear motion. By rolling a circle of radius r along the inner edge of a circle of radius $2r$, such that the circles remain tangent and the smaller circle completes two rotations for every rotation of the larger, a given point on the smaller circle appears to oscillate along the diameter of the larger. The couple was produced as part of Tūsī’s

attempts to address some of the philosophical difficulties of the Ptolemaic model of planetary movements. Applied to the orbs, the couple could potentially allow for the observed variable length of the orbital radius without compromising the principle of uniform circular movement around the earth. Tūsī preferred this solution to Ptolemy's *equant*, which generated much opposition. Tūsī presented his couple not as a definitive solution but rather as "an indication of a solution," signaling perhaps that this model was only the beginning of a longer investigation to be carried out by his students and commentators. While an ostensible follower of Avicennan philosophy, Tūsī appeared to have taken a less radical approach to dealing with the Ptolemaic model than Avicenna (d. 1037) and his student al-Juzjānī (d. 1070), preferring to maintain the model for its practical values and attempting to present important modifications that would reconcile its contradictions, as opposed to rejecting the model for one that would conform better with laws of classical natural philosophy – a task that was never accomplished satisfactorily.

In his *Ethics*, Tusi presented ideas about the evolution or "perfection" of species, although his arguments had important ethical, theological, and mystical underpinnings.

Albedo

Mark S. Marley
NASA Ames Research Center, Moffett Field,
CA, USA

Keywords

Clouds · Equilibrium temperature · Planet · Spectroscopy

Synonyms

[Reflectivity](#)

Definition

Albedo is a unitless measure of the reflectivity of an object. Albedo can range between zero and one. Several different types of albedos have been defined, and it is important to appreciate their unique characteristics.

History

Albedo is derived from the Latin “albus” or “white.” The term was first applied to optics by Johann Heinrich Lambert (who gave his name to the Lambert disk) in his text *Photometria* in 1760.

Overview

From a planet-wide perspective, the albedo of most importance is the Bond albedo, A , the ratio of incident energy reflected into all angles by a planet to the total incident energy received from its star. The Bond albedo appears in the equation for the equilibrium temperature of a rapidly rotating planet T_{eq} , with radius R receiving an incident flux F ,

$$4\pi R^2 \sigma T_{\text{eq}}^4 = (1 - A)\pi R^2 F, \quad (1)$$

which equates the energy thermally radiated by the planet (left side) to the stellar (solar) energy absorbed. The Bond albedo is frequently (as in Eq. 1) computed by integrating the total reflectivity of a planet over the incident flux from the parent star and thus depends both on the reflectivity spectrum and the spectral type of the star. A planet that efficiently scatters in the blue and absorbs in the red portion of the spectrum will thus have a higher integrated Bond albedo when illuminated by a blue star than by a red star, since a greater proportion of the incident light is scattered away in the former case. However, the Bond albedo can be defined as a function of wavelength, $A(\lambda)$, e.g., Irvine et al. (1968), and is then usually termed the spherical albedo.

The geometric albedo is defined as the ratio of a planet’s reflectivity measured at zero phase angle (opposition) to that of a Lambert disk (which has the same apparent brightness at all viewing angles) of the same radius. The geometric albedo is a function of wavelength and, because it is measured at opposition (when the phase angle $\phi = 0$), does not require information on the dependence of scattering with phase. For a perfectly reflecting Lambert sphere, the geometric albedo is two-thirds and for a semi-infinite purely ► [Rayleigh scattering](#) atmosphere it is three-fourths. Both such idealized, perfectly scattering objects would have a Bond albedo of 1, but the latter atmosphere sends more light directly back to the observer at zero phase angle and thus has a higher geometric albedo. The geometric albedo is a fixed quantity for a given planet, so the computation of the geometric albedo does not depend on the type of incident flux. Other types of albedos have been defined. Great care thus must always be exercised to be certain that the correct albedo is being discussed.

Albedo Feature

Daniela Tirsch
German Aerospace Center DLR, Institute of
Planetary Research, Berlin, Germany

Synonyms

[Regio](#)

Definition

A geographic area on the surface of a [planet](#) or satellite that is distinguished from adjacent terrains by a difference in brightness or [albedo](#).

Classical albedo features have been identified with Earth-based telescopes, while no detailed morphology could be resolved. Time-varying albedo features can be due to seasonal changes, for example, due to frost covers or due to the redistribution of bright dust or dark sand sheets by aeolian activity. Thanks to high-resolution imagery on board of space probes, albedo feature nomenclatures are increasingly replaced with detailed feature descriptions.

Alcohol

Kensei Kobayashi
Yokohama National University, Tokiwadai,
Hodogayaku, Yokohama, Japan

Definition

An alcohol is an organic compound containing a hydroxyl (-OH) group. In the IUPAC nomenclature system, the suffix “-ol” is used in the name of each alcohol. The simplest alcohol is ▶ [methanol](#) (methyl alcohol, CH₃OH), and the most commonly encountered alcohol is ▶ [ethanol](#) (ethyl alcohol, C₂H₅OH) which is contained in alcoholic beverages. Alcohols with three or more carbons have isomers: Propyl alcohol has two isomers, which are propan-1-ol (CH₃CH₂CH₂OH) and propan-2-ol (CH₃CH(OH)CH₃). Many low-molecular-weight alcohols, such as ethanol and propan-2-ol, are used as disinfectants, since they diffuse easily through cell membranes and denaturize proteins. Compounds whose hydroxyl group is connected to benzene ring are referred to as phenols.

Aldehyde

John H. Chalmers
Scripps Institute of Oceanography Geosciences
Research Division, University of California, San
Diego, La Jolla, CA, USA

Definition

Aldehydes are organic compounds containing the RCHO functional group where R can be hydrogen or another carbon-containing moiety. Aldehydes are named after the corresponding carboxylic acids by dropping the -ic or -oic suffix and adding

-aldehyde or -al (e.g., acetic acid ► [acetaldehyde](#), ethanoic acid → ethanal), or if derived from acyclic aliphatic hydrocarbons, by dropping the final e and adding -al (e.g., propane → propanal). Formyl derivatives of ring compounds may be called carbaldehydes as in cyclopentanecarbaldehyde. See the IUPAC rules for more complex cases.

Aldehydes can be reduced to alcohols or oxidized to carboxylic acids and undergo a variety of addition and condensation reactions, for example, addition of cyanide in the cyanohydrin synthesis, or condensation with another aldehyde in a benzoin reaction or condensation with the carbon adjacent to an aldehyde or ketone in the aldol reaction.

History

The name may be derived from the phrase ► “[alcohol](#) dehydrogenatum.”

Seaweeds

Synonyms

[Photosynthetic eukaryotes](#); [Protists with chloroplasts](#)

Definition

The algae are an eclectic grouping of photosynthetic eukaryotes that ranges from microscopic picoeukaryotes (~1 μm) (Courties et al. 1994) to

macroscopic multicellular seaweeds (50 m) (Sze 2003). Algae are phylogenetically and morphologically diverse, occur in benthic and planktonic forms, and can be free living, symbiotic, predatory, or parasitic. They inhabit diverse environments including several extreme environments of astrobiological interest, such as desert varnish, permafrost, and highly acidic Mars analog environments (Seckbach 2007). Green algae have unicellular members that share common ancestry with land plants (Charales). Eukaryotic algae along with cyanobacteria dominate global oceanic primary production.

History

The term “blue-green algae” is a colloquial term and refers to cyanobacteria that are members of the domain Bacteria. This term is seldom used in current literature but is still frequently encountered in popular articles and other media.

Overview

Algae are differentiated by various means, including phylogenetic affiliation, photosynthetic pigment type, and morphological features including: the number of flagella, external ornamentation (e.g., scales, frustules), subcellular ultrastructure, and colony-forming abilities. They are polyphyletic and possess representatives in several major lineages of the Eukarya including alveolates (e.g., dinoflagellates), chlorarachniophytes (e.g., *Chlorarachnion*), cryptomonads, euglenids, glaucophytes (e.g., *Cyanophora*), haptophytes (e.g., *Emiliania huxleyi*), red algae (Rhodophyta), stramenopiles (e.g., diatoms, brown algae), and Viridiplantae (e.g., Chlorophyta).

Newer taxonomic classifications based on molecular phylogenetic methods employing multigene approaches place representatives from these lineages into higher taxonomic level groupings called supergroups (Keeling et al. 2005). These six major supergroups are the “Plantae,”

“Chromalveolata,” “Rhizaria,” “Excavata,” “Amoebozoa,” and “Opisthokonta” – the first four of these contain algal representatives. Plantae (also referred to as the Archaeplastida (Adl et al. 2005)) include the red algae, green algae, and streptophytes; Chromalveolata include alveolates and stramenopiles; Excavata include euglenids; Rhizaria include chlorarachniophytes that group within the Cercozoa. A note of caution is that the resilience of these supergroups has been called into question (Parfrey et al. 2006; Yoon et al. 2008), so it is important to take this into consideration when using these terms. Of these six major supergroups, only the Opisthokonta appear to be strongly supported in robust phylogenetic analyses.

In addition to chlorophyll a, algae are further distinguished on the basis of other types of photosynthetic pigments they possess. Alveolates, cryptomonads, haptophytes, and stramenopiles also contain chlorophyll c, while chlorarachniophytes, euglenids, Viridiplantae, and cryptomonads contain chlorophyll b. Other accessory pigments, such as phycobilins, further distinguish cryptomonads, glaucophytes, and red algae.

A feature that all algae share is the ability to photosynthesize. There is strong evidence that this characteristic was the result of a single endosymbiotic event that occurred between a cyanobacterium and an ancestor of the glaucophytes, red algae, and green algae (including plants) (Keeling 2010). The uptake of both green and red algae by other eukaryotes has occurred multiple times in what is referred to as “secondary symbioses.” In some dinoflagellates, tertiary symbioses can occur via plastid replacement. Plastids are also sometimes stolen and used by their host for brief periods of time by sea slugs, dinoflagellates, as well as other protists, such as ciliates and foraminifera – this process is called kleptoplasty.

Algin

► [Alginate](#)

Alginate

Daniel A. Petrash
 Environmental Geochemistry and
 Biogeochemistry, Czech Geological Survey,
 Prague, Czech Republic

Synonyms

3-(6-carboxy-3,4-dihydroxy-5-phosphanyloxan-2-yl)oxy-4,5-dihydroxy-6-phosphanyloxyoxane-2-carboxylic acid (IUPAC); Algin; Alginic acid; Polymannuronic acid

Chemical Formula

$C_{12}H_{20}O_{12}P_2$

Definition

Alginate is a high molecular weight ($>10^4$ Da), straight-chain hydrophilic polysaccharide comprised of polyuronic acids secreted by brown algae and mucoid bacteria, such as several strains of *Pseudomonas* and *Azotobacter*. For such model microorganisms, the physical properties of alginate are crucial for substrate colonization, osmotic and desiccation stress adaptability, and free radical resilience. Irrespectively of its origin, alginate is composed by alternating α -L-guluronate and β -D-mannuronate monomeric units linked through 1 $\rightarrow$ 4 glycosidic bonds and arranged into repeating homo- and heteropolymeric sequences. Bacterial alginate, however, is partially *O*-acetylated, which is thought as an evolutionary mechanism to alter its metal reactivity and viscosity.

History

Nelson and Cretcher (1929) provide a historical summary on early alginate research. Accordingly, the first attempt at separation of a particular carbohydrate component of algae was reportedly made by Stanford (1883), who extracted a polymerized acid fraction by means of dilute alkali and precipitated it by the addition of mineral acid, after the removal of the alkali-insoluble residue by filtration. This substance was called alginic acid or algin. As reviewed by Sutherland (1972), the compositional resemblance between the exopolysaccharides of some bacterial strains and seaweed alginate had been already noticed by a few researchers in the 1960s. Sutherland (op cit.) further defined “bacterial alginates” as group of bacterial exopolysaccharides that can be enzymatically modified.

Alignment of Dust Grains

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Definition

► [Interstellar dust](#) produces not only extinction of transmitted starlight but also introduces polarization of that light, with a positive correlation between the amount of reddening and the linear polarization. This effect is normally ascribed to the alignment of asymmetric grains in the galactic magnetic field. When the direction of alignment

changes along the line of sight, a circularly polarized component is produced. Consequently, observations of this polarization provide (model-dependent) information on both dust grain properties and on the galactic magnetic field. Various mechanisms have been proposed to produce the grain alignment. Since circularly polarized light could conceivably affect the chiral symmetry of irradiated molecules such as amino acids, it could possibly play a role in producing the observed ► [enantiomeric excess](#) in some meteoritic organics, although this is far from being demonstrated.

Definition

Alkaliphiles are microorganisms that grow optimally or very well at pH values above 9, often between 10 and 12, but cannot grow or grow slowly at the near-neutral pH value of 6.5 (Horikoshi [1999](#)).

Overview

There is no precise definition of what characterizes an alkaliphilic organism. Several microorganisms exhibit more than one optimum pH for growth depending on growth conditions, particularly nutrients, metal ions, and temperature. However, the definition given above is the most extended one.

Many different taxa are represented among the alkaliphiles, including ► [prokaryotes](#) (aerobic ► [bacteria](#) belonging to the genera *Bacillus*, *Micrococcus*, *Pseudomonas*, and *Streptomyces*; anaerobic bacteria from the genera *Amphibacillus*, *Anaerobranca*, and *Clostridium*; halophilic ► [archaea](#) belonging to the genera *Halorubrum*, *Natrialba*, *Natronomonas*, and *Natronorubrum*; methanogenic archaea from the genus *Methanohalophilus*; anaerobic archaea from the genus *Thermococcus*; cyanobacteria; spirochetes; actinomycetes; sulfur-oxidizing and sulfate-reducing bacteria), eukaryotes (► [yeasts](#) and filamentous ► [fungi](#)), and even phages (Horikoshi 1998, 1999).

Alkaliphiles require alkaline environments and, in most cases, sodium ions for their growth, germination, and sporulation (Kudo and Horikoshi 1983). Isolation of alkaliphilic microorganisms in laboratory conditions must be carried out in alkaline media containing sodium carbonate, sodium bicarbonate, or sodium hydroxide, following conventional means. Alkaliphiles are widely distributed in different habitats and isolated from soils, feces, and alkaline and/or saline lakes. The frequency of alkaliphilic microorganisms in neutral “ordinary” soil samples is 10^2 – 10^5 /g of soil, which corresponds to 1/10 to 1/100 of the population of the neutrophilic microorganisms (Horikoshi 1991). Some studies show that alkaliphilic bacteria have also been found in deep-sea sediments collected from depths of up to 10,898 m in the Mariana Trench (Takami et al. 1997).

Most alkaliphiles have an optimal growth at around pH 10, which is the most significant difference from well-investigated neutrophilic microorganisms. These alkaliphilic microorganisms can grow in such extreme environments because their internal pH is maintained at 7.5–8.5, despite a high external pH of 8–13 (Aono et al. 1997). Therefore, one of the key features in alkaliphily is associated with the cell surface, which discriminates and maintains the intracellular neutral environment separate

from the extracellular alkaline environment. Alkaliphiles have two mechanisms of cytoplasmic pH regulation. The first one involves the cell wall structure, which contains acidic polymers that function as a negatively charged matrix and may reduce the pH value at the cell surface (Aono and Horikoshi 1983). The surface of the cytoplasmic membrane must presumably be kept below pH 9, because the cytoplasmic membrane is very unstable at alkaline pH values (pH 8.5–9.0) much below the pH optimum for growth (Aono et al. 1992). The second strategy to maintain pH ► [homeostasis](#) consists of the use of the Na^+/H^+ membrane antiporter system ($\Delta\psi$ dependent and ΔpH dependent), the K^+/H^+ antiporter, and ATPase-driven H^+ expulsion (Krulwich et al. 1998).

The flagella motility of alkaliphiles is considered to be driven by a sodium-motive force instead of a proton-motive force, as shown by neutrophiles. These alkaliphiles are most motile at pH 9.0–10.5, whereas no motility is observed at pH 8; in addition, they require Na^+ for motility (Horikoshi 1998).

Studies of alkaliphiles have led to the discovery of many types of enzymes that exhibit interesting properties. Alkaliphilic microorganisms produce some enzymes such as proteases, amylases, cyclomaltodextrin glucanotransferases, pullulanases, cellulases, lipases, xylanases, pectinases, chitinases, and alginate lyases that are of great interest (Horikoshi 1999; Kobayashi et al. 2009).

ALMA

Stuart A. Corder

Joint ALMA Observatory, National Radio Astronomy Observatory, Santiago, Chile

Keywords

Array · Atacama · Interferometer · High frequency · Millimeter/Submillimeter wavelength · Radioastronomy

Acronyms

Atacama Large Millimeter/Submillimeter Array

Definition

ALMA, an international astronomy facility, is an interferometric array of 66 antennas of 12-m (54) and 7-m (12) diameters. ALMA collects and delivers high-quality datasets to the scientific community while further developing the observatory to explore the universe in the millimeter/submillimeter wavelength range. Each antenna is (or will soon be) equipped with receivers covering the transparent atmospheric windows between 35 and 950 GHz and the signals are processed by one of two correlators. ALMA is located at 5000 m elevation in Northern Chile near San Pedro de Atacama on the Chajnantor, a place sacred to the local Likan Antai people.

History

The construction of the observatory dates back to 2004. However, in the 1980s, the global scientific community had already identified the need for a radiotelescope with the characteristics of the Atacama Large Millimeter/Submillimeter Array (ALMA). Independent projects began with Europe, North America, and East Asia each proposing to build a telescope that would receive

radiation in millimeter and submillimeter wavelengths. In 1995, the three partners represented by the National Radio Astronomy Observatory (NRAO), the European Organization for Astronomical Research in the Southern Hemisphere (ESO), and the National Astronomical Observatory of Japan (NAOJ) ran site tests in the Chilean plains, with positive results. Consequently, in 1999, Europe and North America signed a Memorandum of Understanding, and 2 years later in Tokyo a resolution was signed to support the joint intent to construct ALMA between Europe, North America, and Japan.

At the end of 2003, the first stone was placed in what was to become the most ambitious radio observatory on Earth. ALMA construction was completed officially in 2013 with the inauguration of the telescope array. The operations phase for ALMA started in January 2008, in parallel with late construction, marked by the milestone of “operations” taking the responsibility of the ALMA site. Today, this international astronomy facility is a partnership of ESO, the United States National Science Foundation (NSF) and the National Institutes of Natural Sciences of Japan (NINS), and is funded by ESO on behalf of its Member States, by NSF in cooperation with the National Research Council of Canada (NRC) and the National Science Council of Taiwan (NSC), and by NINS in cooperation with the Academia Sinica of Taiwan (AS) and the Korea Astronomy and Space Science Institute (KASI). ALMA operations are led by ESO on behalf of its Member States; by the NRAO, managed by the Associated Universities, Inc. (AUI), on behalf of North America; and by the NAOJ on behalf of East Asia. The Joint ALMA Observatory (JAO), staffed by the executives and headed by the ALMA Director, provides the unified leadership and management of ALMA operations.

Overview

The ALMA operations are concentrated in the Chilean Andes at an elevation of 5000 m, on a

flat plain known as Chajnantor, or “the launching place” in the dialect of the Likan Antai people who have called the surrounding area home for 12,000 years. The high altitude and geography yield dry skies, which limit the attenuation of astronomical submillimeter signals, and the ability to spread the antennas over a large, flat area. Technical operations support is located, locally, at 3000 m near the towns of Toconao and San Pedro de Atacama. Operations are also supported in Santiago, Chile, and in the ALMA Support Centers (ASCs). The ASCs, operated and managed by the respective executives, provide the support and necessary scientific and technical interactions between the respective regional user communities and ALMA. ALMA aims to be accessible to users with no previous submillimeter or interferometric experience. The ACSs provided end-to-end support from proposal preparation through data imaging and analysis.

ALMA has already transformed our understanding of the cold universe, with over 2600 refereed papers with over 82,000 citations as of January 2022. ALMA science spans from the formation of planets to the origins of galaxies. In 2014, ALMA imaged the disk of gas and dust surrounding the forming star HL Tau with unprecedented resolution and quality, revealing a network of gaps and rings in the disk resulting from the planet formation process (ALMA Partnership et al. 2015). A subsequent large program found these structures, and others, to be common place (Andrews et al. 2018), revolutionizing the study of protoplanetary systems. More recently, ALMA participated as a critical element in the first image of a black hole shadow (e.g., Event Horizon Telescope Collaboration 2019), pulling back the veil on the most extreme type of object in the universe. Contributions to star formation studies and cosmology have also been profound (e.g., Dunlop et al. 2017). ALMA is capable of detecting some of the most distant objects in the universe as well (e.g., Hashimoto et al. 2018), with more distant detections coming steadily with time. Currently ALMA is embarking on a ten-year plan to upgrade the system from receivers through the correlator, providing

broader bandwidths and finer spectral resolutions, as well as increasing sensitivity and spectral reach, in order to better understand the origins of galaxies, chemical complexity, and planets.

ALMA is composed of 66 high-precision antennas, 54 of 12-m diameter and 12 of 7-m diameter. The antennas operate in various combinations as an interferometer. The array of 12-m antennas is reconfigured over a biennial cycle with maximum extents ranging up to 16.2 km (giving angular resolutions as fine as $0.012''$). Typically, four 12-m antennas conduct single dish observations and the 7-m diameter antennas operate in a compact, fixed array. Collectively these four 12-m antennas and 7-m antennas are referred to as the Atacama Compact Array (ACA) or the Morita Array. ALMA is currently equipped with eight receivers, with an additional receiver currently being outfitted and a tenth, and final, receiver in development. These ten receiver bands cover all atmospheric windows between 35 and 950 GHz. ALMA's two correlators are capable of generating four tuneable blocks of up to 3840 channels each with bandwidths from 1875–58.6 MHz, for a finest effective channel width of 15 kHz ($\sim$ a few km/s depending on band). The maximum bandwidth in continuum mode is 8 GHz per polarization. This combination allows for detection of thermal emission from dust grains with high sensitivity over a broad frequency range. It also provides the ability to spatially and kinematically resolve spectral emission from a variety of chemical species. For more information, see the ALMA science portal.

Alpha Centauri Bb

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Definition

Alpha Centauri Bb is a putative planet orbiting the star Alpha Centauri B. Alpha Centauri is a triple stellar system consisting of a moderately close binary α Cen AB, and a distant M dwarf companion known as Proxima Centauri at approximately 15,000 AU away from the binary. At a distance of 4.37 light years from the Sun, α Centauri is the closest stellar system to the solar system and is located in the southern constellation of Centaurus. The binary system has a semi-major axis of 23.5 AU and an eccentricity of 0.518. The component A of this system is a G2V star (see ► [Spectral Type](#)) with a mass of 1.1 solar-masses, a luminosity of 1.519 times solar, and an effective temperature of 5790 K. Its component B has a spectral type of K1V and its mass, luminosity, and effective temperature are equal to 0.934 solar-mass, 0.5 solar luminosity, and 5214 K, respectively.

In 2012, a team of scientists lead by Xavier Dumusque announced the detection of a 1.13 Earth-mass planet around α Cen B. One year later, the existence of this planet, known as α Cen Bb, was questioned in an article by Artie Hatzes (2013).

The probable existence of α Cen Bb would indicate that, unlike the region around α Cen A where terrestrial planet formation encounters complications, as predicted by several researchers, planet formation around α Cen B may be efficient.

Note that a planet has been detected around the M dwarf companion Proxima Centauri. This planet is called Proxima-b, has a minimal mass of 1.3 Earth mass and orbits in the habitable zone of Proxima Centauri.

Alpha Helix

John H. Chalmers

Scripps Institute of Oceanography Geosciences
Research Division, University of California, San
Diego, La Jolla, CA, USA

Definition

The alpha (or α -) helix is one of the two most common ► [polypeptide](#) secondary structural motifs and consists of a right-handed helix with 3.6 amino acid residues per turn. The helix has a pitch of 0.54 nm and a width of 1.2 nm and is stabilized by ► [hydrogen bonds](#) between the peptide -C=O- and -NH- moieties of every

fourth bond. The amino acids proline and glycine tend to kink or break alpha helices, whereas alanine, leucine, methionine, lysine, and glutamate stabilize them. Protein alpha-helical regions often fold into coil-coiled configurations that can span membranes, bind DNA, or serve structural roles.

History

The term alpha helix was coined by William Astbury in the 1930s. Linus Pauling worked out the structure accurately in 1948.

Alpha Particles

► [Alpha Rays](#)

Alpha Rays

Jun-ichi Takahashi

Faculty of Engineering, Yokohama National
University, Yokohama, Japan

Synonyms

[Alpha particles](#); [Helium nuclei](#)

Definition

An alpha ray is a stream of alpha particles. An alpha particle consists of two protons and two

neutrons bound together into a particle identical to a helium nucleus; it is produced in the radioactive process called alpha decay. Alpha particles, like helium nuclei, have a net spin of zero. The energy of alpha particles varies, depending upon the specific decay reaction, with higher-energy alpha particles being emitted from larger nuclei, but most alpha particles have energies of between 3 and 7 MeV, corresponding to extremely long to extremely short half-lives of alpha-emitting nuclides. They are a highly ionizing form of particle radiation that when resulting from radioactive alpha decay have low penetration depth. Helium nuclei, which form 10–12% of cosmic rays, are usually of much higher energy than those produced by radioactive decay.

Alteration

Nicholas Arndt
ISTerre, Université Grenoble Alpes, Grenoble,
France

Definition

Alteration in geochemistry refers to processes by which the mineralogy, composition, and texture of a rock are changed as a result of re-equilibration under conditions of lower temperature and pressure or through interaction with aqueous or CO₂-rich fluids. The minerals of the original rock, which may be magmatic, sedimentary, or metamorphic, are transformed into an assemblage of low-temperature, usually finer-grained minerals. A typical example is the replacement of magmatic minerals such as olivine, pyroxene, and feldspar by chlorite, clay minerals, or carbonates. ► [Weathering](#) is a type

of alteration that takes place close to the surface through interaction of rock with the atmosphere and with ground- or surface waters. *Alteration* is also used in chemistry and biology (e.g., DNA alterations).

Alunite

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the
Earth System, Montréal, QC, Canada

Synonyms

[Aluminilite \(older name\)](#)

Chemical Formula (Optional)

KAl₃(SO₄)₂(OH)₆

Definition

Alunite is a clay mineral forming solid solutions with jarosite. It is the product of medium-

temperature (80–150 °C) hydrothermal alteration of feldspar-rich volcanic rocks. On Earth, alunite can be found together with kaolinite and quartz in deposits formed by the alteration of rocks by acidic waters from acid sulfate hot springs. These deposits are recognized as candidates for preserving biosignatures. Detection of alunite at *Terra Sirenum*, Mars, could be an indicator of basalt alteration in contact with H₂SO₄-rich water. Alunite and kaolinite layered deposits detected at *Cross Crater*, Mars, are another indication of weathering at the surface of Mars.

Ambipolar Diffusion

Steven W. Stahler
Department of Astronomy, University of California, Berkeley, CA, USA

Definition

Ambipolar diffusion is the slippage of neutral matter in a plasma with respect to an internal magnetic field. This slippage occurs when the ionization fraction is so low that collisions between neutral species and ions become relatively rare. At this point, the neutral atoms can move relative to the ions, which are effectively tied to the magnetic field. Ambipolar diffusion is thought to occur in ► [molecular clouds](#), which are dense enough to shield much of the external, ionizing radiation. The cloud's self-gravity can then cause the gas to condense, in spite of its internal magnetic field. This condensation ultimately leads to star formation.

 Washington, DC, USA
 Georgia Institute of Technology, Center for
 Chemical Evolution, Atlanta, GA, USA

Definition

In chemistry, an amide is an organic compound which contains the functional group or the name given to a type of bond formed from the condensation of a carboxylic acid and an [amine](#). Mono-substituted amides may exhibit the resonance shown in Fig. 1. Some important amides include peptides, urea, and formamide. Amides are also important intermediates in the Strecker amino acid synthesis. Hydrogen bonding between amide functional groups in polypeptide allows the formation of secondary structural motifs such as α -helices and β -sheets. Amides can be hydrolyzed back to the constituent amine and carboxylic acid. Cyclic amides are known as lactams.

Amino group · Carboxyl group

Synonyms

Amino alkanolic acid

Definition

Amino acids are organic molecules that contain at least one primary amino group (NH_2) and one carboxyl group (COOH). The general formula for amino acids with alkyl side chains that have one amino and one carboxyl group, known as amino alkanolic acids, is $\text{C}_n\text{H}_{2n}\text{NH}_2\text{COOH}$.

History

Most of the biologically important amino acids were isolated and characterized in Europe in the early nineteenth century (Vickery and Schmidt 1931). For example, asparagine, the first amino acid discovered, was isolated from asparagus by Vauquelin and Robiquet in 1806. Glycine was isolated by Braconnot in 1820. Laboratory syntheses were developed shortly thereafter.

Overview

The structural isomers with the amino group on the sequential carbon atoms adjacent to the carboxyl group are called α , β , γ , etc. -amino acids. Thus, α -amino acids are 2-amino alkanolic acids, β -amino acids are 3-amino alkanolic acids, etc. General structural formulae for α , β , and γ amino acids are shown in Fig. 1 and Table 1.

The common names of the amino acid isomers with up to five carbon atoms are given in Table 2.

Some amino acids have aromatic side chains: examples are phenylglycine (α -aminophenylacetic acid), phenylalanine (α -amino- β -phenylpropanoic acid), and tyrosine (α -amino- β -(4-hydroxyphenyl)propanoic acid). Amino acids can also have side chains consisting of an indole (a benzene ring linked to a five-membered nitrogen-containing pyrrole ring) or an imidazole (five-membered diunsaturated ring composed of three carbon atoms and two nitrogen atoms at non-adjacent positions): two examples of this type of amino acid found in biochemistry are tryptophan and histidine, respectively.

There are also amino acids with hydroxyl- and sulfur-containing side chains. The common names of some examples of these amino acids are serine (α -amino- β -hydroxypropanoic acid), threonine (α -amino- β -hydroxybutanoic acid), cysteine (α -amino- β -mercaptopropionic acid), and methionine (α -amino- γ -(methylthio)butyric acid). Selenium can also substitute for sulfur in the sulfur-containing amino acids in some organisms.

Some amino acids have more than one amino group (e.g., lysine or α , ϵ -diaminohexanoic acid) and/or more than one carboxyl group: for example, α -aminomalonic acid, aspartic acid

Amino Acid,

Amino Acid, Table 1 The numbers of possible structural isomers for amino alkanolic acids (with the formula $C_nH_{2n}NH_2COOH$) (Henze and Blair 1934)

Number of carbon atoms	Number of possible isomers
2	1
3	2
4	5
5	12
6	31
10	1479

Amino Acid, Table 2 The names of the structural isomers for 2, 3, 4, and 5 carbon amino alkanolic acids

Number of carbon atoms	Common names
2	Glycine
3	Alanine, β -alanine
4	α -Amino- <i>n</i> -butyric acid, β -amino- <i>n</i> -butyric acid, α -aminoisobutyric acid, β -aminoisobutyric acid, γ -amino- <i>n</i> -butyric acid
5	Valine, isovaline, β -aminopentanoic acid, γ -aminopentanoic acid, δ -aminopentanoic acid, α -methyl- β -aminobutyric acid, allo- α -methyl- β -aminobutyric acid, α -methyl- γ -aminobutyric acid, β -methyl- β -aminobutyric acid, β -methyl- γ -aminobutyric acid, α -ethyl- β -aminoproponic acid, α -dimethyl- β -aminoproponic acid

(α -aminobutanedioic acid), and glutamic acid (α -aminopentanedioic acid). Asparagine (α -amino- β -carbamoylpropanoic acid) and glutamine (α -amino- δ -carbamoylbutyric acid) are the side group carboxamides of aspartic and glutamic acids, respectively. Interestingly, asparagine was the first amino acid discovered in 1806 when it was crystallized from the “juice” squeezed from asparagus shoots. The amino acid arginine (α -amino- ϵ -guanidinopentanoic acid) has a guanidinium group attached to the end of its alkyl side chain.

Some amino acids have a cyclic secondary amine rather than a primary amino group.

Amino Acid, Fig. 2 Some cyclic amino acids, proline, and pipecolic acid

Examples include proline (pyrrolidine-2-carboxylic acid, $C_5H_9NO_2$) where the primary amino group is replaced with a five-membered pyrrolidine ring or tetrahydropyrrole and pipecolic acid (piperidine-2-carboxylic acid, $C_6H_{11}NO_2$) where the amino group is replaced by six-membered piperidine ring (Fig. 2).

The ionization constants (pK_a) at 25 °C of the amino and carboxyl groups of amino alkanolic acids are in the range 8–10 and 2–4, respectively. Thus, at neutral pH, the amino group is protonated, while the carboxyl group is deprotonated, producing a doubly charged ► **zwitterion** with no net charge. Amino acids with other amino or carboxyl groups have additional ionization constants characteristic of the particular group. The pK_a of the β -carboxyl group of aspartic acid is 3.9 at 25 °C; thus at neutral pH aspartic acid has a net negative charge. The pK_a of the guanidinium group of arginine is 12.5, and arginine is thus positively charged at neutral pH.

When a carbon atom in an amino acid has four different groups attached to it, referred to as an asymmetric or ► **chiral** carbon, it is optically active. For those amino acids with one chiral carbon, there are two possible optically active isomers designated, the L- and D-enantiomers. Some amino acids have more than one chiral carbon so several stereoisomers are possible. An amino acid with two chiral carbons is said to be diastereomeric, and there are thus two diastereomers, each of which has two enantiomers, for a total of four possible optical isomers. For the diastereomeric pair L-isoleucine/D-alloisoleucine (α -amino- β -methylpentanoic acid), the two sets

Amino Acid, Fig. 3 Enantiomers and diastereomers of iso- and alloisoleucine

of enantiomers are L- and D-isoleucine and L- and D-alloisoleucine, respectively (Fig. 3).

Amino acids can be linked together by the formation of a ► [peptide](#) bond that involves the amino group of one amino acid and the carboxyl group of another. Two amino acids connected in this fashion are called a dipeptide which has the structure given below (in this case, one amino acid is glycine and the other has a generic R-group side chain) (Fig. 4).

Polypeptides and proteins consist of a large number of amino acids connected in peptide linkages. A total of 20 different amino acids (for this discussion, the amino acids selenocysteine and pyrrolysine are not included because they are relatively rare coded amino acids) are decoded from DNA sequences and encoded into RNA for incorporation into proteins. A list of the “canonical” 20 protein amino acids and their abbreviations are given in Table 3. There are peptides that contain additional amino acids other than the standard protein amino acids, but these are incorporated by posttranslational modifications or the

Amino Acid, Fig. 4 A generic dipeptide

Amino Acid, Table 3 The 20 amino acids commonly found in proteins and their commonly used abbreviations

Amino acid common name	Three-letter abbreviation	One-letter abbreviation
Aspartic acid	Asp	D
Glutamic acid	Glu	E

Histidine	His	H
Arginine	Arg	R
Tryptophan	Trp	W
Proline	Pro	P

peptides themselves are synthesized by non-ribosomal peptide synthetases (NRPSs). For example, α -aminoisobutyric acid and isovaline are found in some fungal peptides synthesized by NRPSs.

With the exception of achiral glycine, only the L-enantiomers of the proteinogenic amino acids are incorporated into proteins. The discrimination against the incorporation of D-amino acids during the protein synthesis process is estimated to be greater than 10⁴. However, there are D-amino acids present in some peptides, but these are introduced either by the conversion of L-amino acids by posttranslational isomerization enzymes or are

introduced by NRPSs. Some D-amino acid-containing peptides have potent antimicrobial activity.

The total number of amino acids theoretically possible is huge, and several hundred different amino acids have been isolated from organisms, and an even larger number have been made in the laboratory by a variety of synthetic methods. Moreover, the synthesis of amino acids is not confined to terrestrial biology or laboratory synthesis: amino acids have been detected in meteorites, and there are hints that at least the simplest amino acid glycine is present in interstellar clouds and comets (see ► [Molecules in Space](#)). One of the meteorites most extensively studied is the ► [Murchison](#) carbonaceous chondrite that fell in southeastern Australia in 1969. Over 75 different amino acids have been detected in Murchison (Sephton 2002), with only 8 of these also being found in biological proteins. These amino acids are clearly of extraterrestrial origin: many are unique to the meteorite and do not occur naturally on Earth and those with a chiral carbon are racemic (or close to racemic). The Murchison amino acids are thought to have been synthesized by natural reactions, such as the ► [Strecker synthesis](#), directly on the juvenile meteorite parent body or in the early solar nebula before incorporation into planetesimals. Amino acids have been detected in even larger quantities in other carbonaceous chondrites (Pizzarello and Shock 2010).

Amino acids may also have been synthesized by natural processes on the early Earth as demonstrated by the classic Miller spark discharge experiment carried out in 1953 (Miller 1953; Johnson et al. 2008). These amino acids could have accumulated on the Earth and been available for incorporation into the first living entities. To date, 12 of the amino acids found in the proteins of terrestrial organisms have been synthesized in spark discharge experiments with various reduced gas mixtures.

The striking overlap between amino acids generated in experiments simulating prebiotic chemistry and found in meteorites represents evidence for the abiotic plausibility of approximately half of the canonical amino acid set. This is also supported by the thermodynamics of their

formation (Higgs and Pudritz 2009). Debate continues, however, as to whether these amino acids would have been sufficient to comprise the first functional proteins. It is also unclear how these amino acids came to be used by life when many others might have been also available (Weber and Miller 1981; Cleaves 2010).

The amino acids absent from abiotic simulations and meteorites are not only difficult to make but are also either thermally unstable (Gln, Asn) or are unstable under UV conditions (Cys, Met, Trp, His, Tyr, Phe). This strongly suggests that these amino acids are biological “inventions” and their multi enzymatic synthesis pathways appeared only after the onset of Darwinian evolution. The order of biologically invented amino acid entering the code has been hypothesized based on thermodynamics (Higgs and Pudritz 2009); however, the entry and retention of amino acids is likely to be complex, with such factors as accessibility, compatibility, complementarity with existing code members, and stability on transfer RNA all playing a role (Weber and Miller 1981; Cleaves 2010). The culmination of this selection is a set of amino acids unchanged since the last universal common ancestor (LUCA), which is exceptional in breadth and evenness in terms of size, hydrophobicity, and charge (Philip and Freeland 2011).

Amino Acid *N*-Carboxy Anhydride

Laurent Boiteau
Institut des Biomolécules Max Mousseron,
UMR5247 CNRS, University Montpellier-2,
Montpellier, Cedex, France

Synonyms

1,3-Oxazolidine-2,5-dione; Leuchs' Anhydride; NCA

Definition

An amino acid *N*-carboxy anhydride (or NCA) is a cyclic organic compound structurally related to an ► [amino acid](#), which is an intramolecular mixed anhydride of a carboxylic and carbamic acid (structure -CO-O-CO-NH-), making it both an *N*-protected and a *CO*-activated amino acid. NCAs are structurally related to hydantoins but have very different chemical reactivity. They are rather unstable in water and physiological media. The term NCA is usually used to refer to the

NCAs of α -amino acids (although NCAs of β -amino acids etc. are also possible). NCAs can condense to give oligo- or polypeptides, with the release of CO₂. NCAs are postulated or observed intermediates in many prebiotically relevant reactions leading to ► [peptides](#) from amino acid derivatives, especially in aqueous media in the presence of carbonate. NCAs are also considered to be potentially prebiotic reagents, as they are versatile free energy carriers which can potentially activate other biologically relevant chemical species, such as nucleotides.

History

Although speculations that NCAs might have played a role in prebiotic chemical evolution arose in the mid-1970s, notwithstanding their use since the late 1970s in “model” prebiotic reactions, studies in the early 2000s improved the status of NCAs as prebiotically relevant compounds.

Overview

Discovered by Hermann Leuchs in 1906, NCAs are well-known reactants in both organic and polymer synthesis (Kricheldorf 2006). Since their most popular preparative method involving the reaction of free amino acids with phosgene is *not* prebiotically relevant, NCAs themselves were long considered as prebiotically irrelevant (Pascal et al. 2005). Nevertheless, NCAs have been continuously used from the 1970s in model reactions of prebiotic peptide formation, especially to assess stereoselection hypotheses in relation with the emergence of *homochirality* of the natural amino acid pool, e.g., enantiomeric excess amplification processes (Kricheldorf 2006; Pascal et al. 2005; Illos et al. 2008). NCAs have long been postulated as likely intermediates in the reaction of activated amino acid esters (e.g., adenylates, thioesters) based on the observation that the formation of peptides is accelerated by the presence of CO₂ or bicarbonate. Since the late 1990s, several prebiotically relevant pathways for NCA

formation have been identified, thus confirming the prebiotic status of NCAs (Kricheldorf 2006; Pascal et al. 2005):

- The nitrosation of *N*-carbamoyl amino acids (CAA) promoted by nitrogen oxides (Kricheldorf 2006; Pascal et al. 2005).
- The decomposition of diacyldisulfides
- The reaction of amino acids with carbonyl sulfide in the presence of oxidizing or alkylating agents (Leman et al. 2004).
- The spontaneous decomposition of CAA in water (Danger et al. 2006).

NCAs represent both (1) the structurally simplest activated amino acids (formally resulting from condensation with CO₂), (2) an unavoidable intermediate from any form of CO-activated amino acid in a bicarbonate/CO₂-rich environment, and (3) the most activated amino acid species achievable in water in a prebiotic environment. Thermodynamic calculations show NCAs to be quite stable (because of the cyclic structure) compared to other anhydrides, although kinetically they are as reactive as the latter. Furthermore, NCAs may be kinetically competent intermediates from almost any inactivated amino acid derivatives, provided their spontaneous hydrolysis is slower than NCA formation (Pascal et al. 2005).

Such thermodynamic and kinetic features make NCAs potential *energy carriers* in an amino acid-based protometabolism, as exemplified by their ability to activate inorganic phosphate (Pascal et al. 2005) or nucleotides (Biron et al. 2005; Leman et al. 2006), which could be coupled to a peptide/nucleic acid coevolution scenario supporting speculations on the emergence of the translation apparatus (Pascal et al. 2005).

Amino Acid Precursors

Kensei Kobayashi
Yokohama National University, Tokiwadai,
Hodogayaku, Yokohama, Japan

Definition

► **Amino acid** precursors are compounds that give amino acids after some reactions (usually hydrolysis). One of the typical amino acid precursors is ► **aminoacetonitrile**, which is converted to glycine by hydrolysis via glycine ► **amide**:

$$\text{NH}_2\text{CH}_2\text{CN} + 2\text{H}_2\text{O} \rightarrow \text{NH}_2\text{CH}_2\text{CONH}_2 + \text{H}_2\text{O} \rightarrow \text{NH}_2\text{CH}_2\text{COOH} + \text{NH}_3.$$
 Hydantoins (substituted glycolylurea) are also typical amino acid precursors and have been found in carbonaceous chondrites. Complex organic polymers with large molecular weights are also possible precursors. ► **Tholins**, which are formed by reactions of

mixtures of nitrogen and methane, are large complex molecules which give amino acids after hydrolysis. Amino acids are frequently detected in carbonaceous ► [chondrites](#) (meteorites), but the amount of amino acids recovered usually increases after hydrolysis, suggesting that some amino acids are present in the form of amino acid precursors.

Aminobutyric Acid

Mark Dörr
University of Southern Denmark, Odense M,
Denmark

Synonyms

[Butyrine](#); [Ethyl-glycine](#)

Definition

Aminobutyric acid is the term for a variety of structural isomers of amino acids derived from *n*- or isobutyric acid with the chemical formula $C_4H_9NO_2$. They belong to the substance class of amino acids, since they contain an amino functional group and a carboxylic acid functional group. In nature, several different isomers of aminobutyric acid are found: (1) α -aminobutyric acid (α ABA), a key intermediate in the biosynthesis of ophthalmic acid, (2) β -aminobutyric acid (β ABA), (3) γ -aminobutyric acid (GABA), which modulates the excitability of neurons of vertebrates and muscle tone, and (4) α -aminoisobutyric acid (α AIB), which is found in some fungal membrane peptides. Several aminobutyric acid isomers have been found in carbonaceous chondrite meteorites.

α , β , and γ denote the position of the amino group relative to the carboxyl group in the ► [amino acid](#) molecule: α refers to the first, β the second, and γ the third position.

Definition

Amino isobutyric acid (AIB) is an amino acid derived from isobutyric acid. There are two structural isomers of amino isobutyric acid (Fig. 1), α -aminoisobutyric acid (α AIB), which is achiral, and β -aminoisobutyric acid (β AIB), which has two ► [stereoisomers](#), a D and L form. Both isomers have been found in carbonaceous chondrites, with α AIB often being one of the most abundant amino acids. This is thought to be significant as α AIB is not found in proteins, suggesting an extraterrestrial origin of this compound. However, several fungi are now known to

Acronyms

AMN

Definition

Aminomaleonitrile is a likely prebiotic molecule. It is a reactive intermediate in formamide- and hydrogen cyanide-based prebiotic syntheses of nucleic acid bases (Ruiz-Bermejo et al. [2013](#); Hudson et al. [2012](#)) and HCN oligomers (Moser et al. [1967](#)). AMN is synthesized from iminoacetoneitrile, in basic (1–11 M) HCN solutions (Oró and Kimball [1962](#)). Further condensation affords 2, 3-diaminomaleonitrile (DAMN). Reaction with formamidine results in the synthesis of 5-aminoimidazolecarbonitrile (AICN). This

reaction pathway is involved in prebiotic syntheses initiated by heat (Saladino et al. 2005), electric discharges (Hoerst et al. 2012), or impact event (Ferus et al. 2020).

History

According to Miller (1953), the synthesis of purines and pyrimidines remains a hurdle for understanding of the origin of life. In 1960, Oró demonstrated the synthesis of adenine from ammonium cyanide (Oró 1960). AMN has been identified as an intermediate of basic HCN-based synthesis in 1962 (Oró and Kimball 1962); however, it also participates in one-pot prebiotic synthesis of nucleobases as suggested by Saladino and Di Mauro (Saladino et al. 2006), as well as by meteoric impact-like processes (Ferus et al. 2017).

Definition

The Amitsoq gneisses are among the older metamorphic rock complexes yet discovered on Earth. These rocks outcrop on the southwestern coast of Greenland, where they extend over more than 50 km northeast of Nûk (Godthåb). The oldest age obtained on a zircon crystal extracted from a tonalitic gneiss sample is of 3.872 ± 0.010 Ga.

Overview

The Amitsoq gneisses outcrop on the southwestern coast of Greenland, where they extend over more than 50 km northeast of Greenland's capital Nûk (Godthåb), along the southern coast of the Godthåbsfjord. After long and detailed field work, Mc Gregor (1968, 1973) was the first who recognized these Archaean terrains as among the oldest in the world. He distinguished two groups of gneisses: (1) very old ones cut by mafic dykes (Ameralik dykes) that he called the Amitsoq gneisses, (2) younger ones emplaced after the Ameralik dykes and that are referred as the Nûk gneisses. Both groups are crosscut by the late Qôrqt granite. The first dating of the Amitsoq gneisses was conducted by Black et al. (1971), who obtained a Rb-Sr isochron age of 3.98 ± 0.17 Ga, and Moorbath et al. (1972), who measured a slightly younger age (3.74 ± 0.1 Ga) using the same method. Newer researches showed that the so-called Amitsoq gneisses were heterogeneous and made up of several intrusive bodies. In order to account for this diversity, Nutman et al. (1996) proposed to refer to these formations as the Itsaq Gneiss Complex. In fact, both terms are equivalently used in geological literature.

This view has been subsequently corroborated by intensive zircon dating. Nutman et al. (1996) and Nutman and Hiess (2009) determined that the emplacement of Amitsoq gneiss protolith (protolith

Amitsoq Gneisses,

Fig. 1 General view of the ~3.8 Ga Amitsoq gneisses. They consist in grey gneiss, TTG in composition. (On this photo, they are crosscut by a black Ameralik dyke (Photo G. Gruau))

is the original, unmetamorphosed rock from which a metamorphic rock is formed) occurred between 3.88 and 3.60 Ga, during at least three main petrogenetic episodes at ~3.80 Ga, ~3.7 Ga, and ~3.65 Ga. It must be noted that some ages older than 3.85 Ga were also measured (Horie et al. 2010; Nutman et al. 2013). Indeed, a zircon crystal extracted from a tonalitic gneiss sample gave an age of 3.872 ± 0.010 Ga, which is the oldest reliable age so far measured in Amitsoq gneisses. The same authors reported an age of 3.883 ± 0.009 Ga measured in a zircon core, while the rim provided a slightly younger age of 3.861 ± 0.022 Ga; these dates are assumed as those of parental magma crystallization.

The Amitsoq gneisses outcrop over vast areas, over about 3,000 km². Their protolith was a felsic plutonic rock, having a tonalitic, trondhjemitic, and granodioritic (TTG) composition (O’Nions and Pankhurst 1978; Nutman and Bridgwater 1986; Nutman et al. 2000, 2007, 2013; Steenfelt et al. 2005; Hiess et al. 2009). In Archaean terrains, TTGs are very abundant; these are by far the most abundant rocks of the Archaean continental crust (Moyen and Martin 2012). They are generated by partial melting of hydrous basalt, possibly in a subduction-like environment (Martin 1986; Martin et al. 2005, 2014). Subsequently, they underwent granulite facies metamorphism at about 3.6 Ga (Friend and Nutman 2005).

Before the Cretaceous, and the development of the Labrador ridge and the Baffin Bay basin, west

Greenland and Labrador were closer to each other. At that time, Archaean terrains on both sides should have been connected. Indeed, along the northern coast of Labrador outcrop the Uivak gneisses, which are metamorphic rocks, mostly TTG in composition and very similar to the Amitsoq gneisses. The Uivak gneisses contain zircon crystals dated at 3.733 ± 0.009 Ga; however, they also contain rounded cores dated at 3.863 ± 0.012 Ga (Bridgwater and Collerson 1976; Bridgwater and Schiøtte 1991). Contrarily to Greenland, in Labrador these rocks suffered a Neoarchaean granulite facies metamorphism (Collerson and Bridgwater 1979) (Fig. 1).

Ammonia

Alexander Smirnov

Department of Earth and Marine Science,
Dowling College, Oakdale, NY, USA

Keywords

Prebiotic synthesis · Nitrogen · Abiotic reduction

Synonyms

Azane; Nitro-sil; Trihydrogen nitride

Definition

Ammonia (NH₃) is a chemical compound composed of ► **nitrogen** and hydrogen which exists as a gas at standard conditions of temperature and pressure. In the trigonal pyramidal ammonia molecule, the lone electron pair of the nitrogen atom is responsible for its dipole moment (polarity) and its behavior as a base (proton acceptor). It dissolves readily in water and its protonation results in the formation of the conjugate acid ammonium ion (NH₄⁺) with both species coexisting in a pH-dependent equilibrium (pK_a NH₄⁺ = 9.25 at 25 °C). Liquid ammonia (boiling point –33.35 °C at atmospheric pressure) is an ionizing solvent

with physical properties and behavior similar to water (Lagowski 2007).

History

Ammonia has been known since ancient times, although it was first isolated by Priestly in 1774. In 1785, Berthollet determined its composition. The Haber-Bosch process to synthesize ammonia from nitrogen and hydrogen was developed by Fritz Haber and Carl Bosch in 1909. It was found in space by Cheung et al. (1968) and in comets by Altenhoff et al. (1983) using radio-astronomical techniques.

Overview

Ammonia has been detected throughout our solar system as well as in interstellar space (see ► [Molecules in Space](#)). The deuterated ammonium ion NH_3D^+ has recently been detected in the interstellar medium (Cernicharo et al. 2013; note that the symmetry of the principle isotopic form, NH_4^+ , leads to a zero electric dipole moment and hence no pure rotational transitions that might be observed astronomically). Ammonia is found as a gas in planetary atmospheres and in the solid form (ice) in cometary nuclei and planetary surfaces. Ammonia is hypothesized to be present in liquid form in a subsurface ocean on some outer planet satellites (e.g., ► [Titan](#)) where it would effectively lower the freezing point of water (Raulin 2008).

On the early Earth, ammonia was likely a necessary precursor for prebiotic organic synthesis, such as the ► [Strecker synthesis](#) of amino acids. It was used as the nitrogen source in the Miller-Urey experiment, which produced a suite of organic compounds such as amino acids from a mixture of reduced gases simulating the primordial atmosphere (Miller 1953). However, most current models suggest the early atmosphere was only mildly reducing, with the redox state linked to the evolution and oxidation state of the Hadean and early Archaean mantle, with ► [dinitrogen](#) (N_2) as the dominant nitrogen species (Kasting and Catling 2003).

It has been experimentally shown that ammonia-containing environments are more

efficient in organic synthesis than those dominated by dinitrogen in both aqueous and gaseous environments. This notion is not unexpected, considering that the strong triple bond (948 kJ.mol^{-1}) of the N_2 molecule results in large reaction activation energy barriers even if the overall reaction is thermodynamically favored. The process of conversion (e.g., reduction) of unreactive dinitrogen to reactive and prebiologically useful ammonia is referred to as ► [nitrogen fixation](#).

Mechanisms suggested for abiotic ammonia production on the early Earth include reduction of atmospherically derived nitrite (NO_2^-) by ferrous iron or iron-bearing minerals (Summers and Chang 1993); hydrolysis of atmospherically produced HCN (Zahnle 1986); reduction of dinitrogen on mineral surfaces (sulfides, metals, alloys) in hydrothermal systems (Brandes et al. 2008; Smirnov et al. 2008; Singireddy et al. 2012); or delivery of reduced nitrogen (nitride, N^{3-}) in iron meteorites followed by dissolution and reaction with H^+ (Smirnov et al. 2008). The concentrations of ammonia and/or ammonium ion in the prebiotic atmosphere and hydrosphere were likely controlled by mechanisms such as photolytic destruction, sequestration in clay minerals by substitution for K^+ and formation of N-bearing organic molecules.

Amoebae

Emmanuelle J. Javaux
Palaeobiogeology-Palaeobotany-
Palaeopalynology, Geology Department,
Université de Liège, Liège, Belgium

Definition

Amoebae are microscopic unicellular eukaryotes (► [Protists](#)) able to deform their cytoplasm to move (amoeboid or crawling-like movement). They represent a large diversity of unrelated groups of eukaryotes. Some are surrounded by a cell coat (glycocalyx); others are naked. Some are pathogens. Others produce a mineral test made of siliceous plates, an organic test, or an agglutinated test made of external organic or mineral particles (thecamoebae or testate amoebae). Some amoebae demonstrate a social behavior when several individuals join to form

complex multicellular structures such as slugs or fruiting bodies. The oldest fossil amoeba reported so far is 750 Ma old.

Amorphous Carbon

Akira Kouchi

Institute of Low Temperature Science, Hokkaido University, Kita-ku, Sapporo, Hokkaido, Japan

Keywords

Amorphous carbon · Carbon star · Carbonaceous chondrites · Cometary particles · Hydrogenated amorphous carbon · Interplanetary dust particles

Synonyms

[Glassy carbon](#); [Vitreous carbon](#)

Definition

Amorphous carbon is a noncrystalline solid allotropic form of carbon. There is no long-range order in the positions of the carbon atoms, but some short-range order is observed. Chemical bonds among atoms are a mixture of sp^2 - and sp^3 -hybridized bonds with a high concentration of dangling bonds. Because amorphous carbon is thermodynamically in a metastable state and the ratio of sp^2 - and sp^3 -hybridized bonds is variable, the properties of amorphous carbon vary greatly depending on the formation methods and conditions (Silva and Ravi 2003). Amorphous carbon is often abbreviated as “*a-C*.”

Overview

In the laboratory, amorphous carbon can be produced by physical vapor deposition, chemical vapor deposition, sputtering, and ion irradiation of diamond or graphite. The structure of amorphous carbon has been analyzed by X-ray and electron diffraction methods. The ratio of sp^2 - and sp^3 -hybridized bonds can be determined by electron energy loss spectroscopy, X-ray photoelectron spectroscopy, and Raman spectroscopy. Amorphous carbon whose dangling bonds are terminated with hydrogen is called hydrogenated amorphous carbon (*a-C:H*). Depending on the sp^2 and sp^3 ratios, the properties of amorphous carbon differ greatly. When a significant fraction of sp^3 bonds is present in amorphous carbon, this is called tetrahedral amorphous carbon (*ta-C*) or diamond-like carbon. Tetrahedral amorphous carbon is hard, transparent, and electrically insulating and has higher density than *a-C* and *a-C:H*.

In space, the occurrence of amorphous carbon is observed in circumstellar envelopes around carbon stars. When carbon stars lose mass to stellar winds, carbonaceous materials, such as polycyclic aromatic hydrocarbons (PAH), SiC, and amorphous carbon (*a-C/a-C:H*), that condense in their extended atmospheres are released to the interstellar medium. The conditions for the formation of amorphous carbon (*a-C*) grain have been investigated theoretically (Gail and Sedlmayr 1984), and the occurrence of amorphous carbon (*a-C*) and SiC has been deduced by observing the spectra of carbon stars (Blanco et al. 1990).

Very recently, amorphous carbon has been found in various extraterrestrial materials. Cometary particles from comet 81P/Wild 2, captured by NASA's Stardust mission, were analyzed by transmission electron microscopy, and a small amount of amorphous carbon grains less than 200 nm in size was found (Matrajt et al. 2008). In interplanetary dust particles (IDPs), investigated with Raman and infrared spectroscopy, the dominant type of carbon is found to be either a form of amorphous carbon (*a-C*) or of hydrogenated amorphous carbon (*a-C*:

H), depending on the type of IDP (Muñoz Caro et al. 2006). It has been proposed that amorphous carbon in cometary particles and IDPs was formed by energetic processing (UV photons and cosmic rays) of icy grains in interstellar molecular clouds (Greenberg 1998; Kouchi et al. 2005). Amorphous carbon grains have also been found in the matrix of carbonaceous chondrites (Brearley 2008). These grains are essentially made of pure carbon embedded in an amorphous silicate matrix. It has been proposed that these grains were originally primitive macromolecular organic material that has undergone mild thermal metamorphism in the parent bodies of carbonaceous chondrites.

Amorphous Solid

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Definition

An amorphous solid lacks long-range order in the positioning of its constituent atoms; glass is an example. This contrasts with a crystalline solid, where such order is present, e.g., quartz. Both the ices and the silicates in ► [interstellar dust](#) grains are typically amorphous, although crystalline silicates are present in some circumstellar and cometary dust. The conversion of amorphous to crystalline water ice has often been invoked as an energy source in cometary outbursts at large heliocentric distances. The presence of crystalline silicates (presumably formed in the hot and dense inner solar system, possibly under the action of energetic particles from the young Sun) in ► [comets](#), which are formed in the cold outer part of the solar system, suggests that mixing of material was important in the ► [solar nebula](#).

Amphibolite Facies

Nicholas Arndt

ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Amphibolite facies refers to one of the divisions of the mineral-facies classification of the ► [metamorphic rocks](#). It corresponds to rocks

formed under moderate to high temperatures (400–600 °C) and pressures (200–900 MPa) conditions. Rocks in most Archean granulite-gneiss belts are metamorphosed to the amphibolite facies or higher. The name-giving rock is amphibolite, a dense and dark green to black rock generated by metamorphism under moderate temperature (ca. 500 °C) and pressure (1 GPa) from a mafic (basaltic) protolith or, more rarely, from impure dolostone (carbonate rock). It contains mainly hornblende, a type of amphibole (a chain silicate mineral group), with lesser proportions of plagioclase (a framework silicate mineral), and in some cases biotite, epidote, titanite, and iron oxides. Amphibolite is a common constituent of metamorphosed ► [oceanic crust](#) or of mafic intrusions in orogenic belts.

Amphiphile

David Deamer
Department of Chemistry, University of
California, Santa Cruz, Santa Cruz, CA, USA

Synonyms

[Detergent](#); [Lipid](#); [Surfactant](#)

Definition

An amphiphile is a molecule having both a hydrophobic nonpolar group and a hydrophilic polar group. The nonpolar hydrophobic portion of the molecule is typically a hydrocarbon chain ranging from 10 to 20 or more carbon atoms in length, and the polar moiety can be a carboxylic acid, phosphate, sulfate, amine, or alcohol group, among

other possibilities. Examples of amphiphiles are fatty acids, detergents, and all lipids including phospholipids and sterols. All amphiphiles are surface active and form monolayers at air-water interfaces. Some amphiphiles, particularly those with a single hydrocarbon chain, assemble into ► [micelles](#) in aqueous solutions. Other amphiphiles with two hydrocarbon chains, for instance, phospholipids, typically self-assemble into bilayer membranes that are the permeability barriers defining most forms of cellular life. Amphiphilic molecules resembling fatty acids are present in carbonaceous meteorites and are plausible membrane-forming components of the first living cells.

Amphiphilicity

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Definition

Amphiphilicity refers to the property of some molecules to have an affinity to two phases and most notably in biochemical systems the affinity to both a polar solvent phase (in this case water) and hydrophobic phase (such as the interior of cell membranes or proteins). Amphiphilic molecules usually contain both hydrophobic (e.g., benzyl or alkyl) and hydrophilic groups (e.g., -OH, -NH₂ and -COOH). Amphiphilic molecules are often useful as surfactants. Sodium dodecylbenzene sulfonate is a typical amphiphilic molecule used as a laundry detergent or shampoo and complexes hydrophobic substances such as dirt and oil with its hydrophobic dodecylbenzene moiety (C₁₂H₂₅-C₆H₄-) and is dispersed by affinity of the sulfonate moiety (-SO₃H⁻) to water.

Amphiphilic molecules can assemble in various solvents. Phospholipids are typical amphiphilic biomolecules, having hydrophilic heads including phosphate ions or charged tertiary or quaternary amines and hydrophobic tails including fatty acids. Many phospholipids form lipid bilayer membranes in water, where the polar heads face toward the solvent and hydrophobic tails which aggregate to form the inner part of the vesicle.

Amphoteric Compounds

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Synonyms

[Ampholytes](#)

Definition

An amphoteric compound is a compound that can act both as an acid and as a base. Some metal oxides or metal hydroxides, such as aluminum oxide (Al_2O_3), show amphotericity:

Some organic compounds also show amphotericity. These include amino acids, compounds having both carboxylic group(s) and amino group(s). For instance, glycine is predominantly present as a zwitterion ($^+\text{NH}_3\text{-CH}_2\text{-COO}^-$) in circumneutral aqueous solution, and it can neutralize either an acid or a base as follows:

Amino acids and their polymers (proteins) dissolved in aqueous solution possess both positively and negatively charged groups. In acidic solution, there are typically more positively charged groups, while there are typically more negatively charged groups in basic solution, though this depends somewhat on the sequence of the protein. At a defined pH called the isoelectric point (pI), amino acids or proteins have balanced positive and negative charges. At the isoelectric point of a protein, its hydrophobicity becomes maximum, and its solubility to water becomes minimum.

Amplification (Genetics)

Carlos Briones
Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

In molecular biology, amplification is a process by which a ► [nucleic acid](#) molecule is enzymatically

copied to generate a progeny population with the same sequence as the parental one. The most widely used amplification method is the ► [polymerase chain reaction](#) (PCR). The result of a PCR amplification of a segment of ► [DNA](#) is called an “amplicon.” Nucleic acids can also be amplified in an isothermal reaction involving a reverse transcriptase, which copies ► [RNA](#)→DNA, and a DNA-dependent RNA polymerase, which transcribes DNA→RNA. Isothermal amplification does not generate double-stranded DNA, and it is mainly used for copying RNA. Ligase-based methods, including the so-called ligase chain reaction (LCR), can be also used for specific DNA or RNA amplification. A fourth general method for nucleic acid amplification involves ► [cloning](#) the selected DNA molecule into bacterial or eukaryotic cells, allowing them to reproduce, and collecting the amplified DNA.

Anaerobe

José Luis Sanz
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Non-aerobic](#)

Definition

Anaerobes are organisms that do not require oxygen to obtain energy or to grow. Anaerobic metabolism is restricted to microorganisms, both prokaryotic (► [Bacteria](#) and ► [Archaea](#)) and eukaryotic (yeast, microsporidia), although an anaerobic multicellular organism (phylum *Loricifera*) has been recently discovered in marine sediments.

Overview

There are two main categories of anaerobic microorganisms: (1) facultative anaerobes that can use oxygen for ► [respiration](#) if it is present but in its absence obtain energy from ► [fermentation](#) (such as enterobacteria or yeasts), ► [anaerobic respiration](#) (some *Pseudomonas*, *Thiobacillus*, *Bacillus*, and many others), and anoxygenic photosynthesis (some *Proteobacteria*) and (2) obligate anaerobes, which never use oxygen. These can, in turn,

be divided into two subcategories: (a) strict or obligate anaerobes, for whom oxygen is poisonous (i.e., oxygen is extremely toxic to ► [methanogens](#)), and (b) aeroduric or aerotolerant anaerobes that can grow in the presence of oxygen, although they never use it (i.e., bacteria involved in lactic acid fermentations). Cultivating strict anaerobes in the laboratory is an arduous task due to their extreme sensitivity to oxygen. Anaerobic jars or chambers are necessary for the isolation and growth of methanogenic archaea, sulfur-reducing bacteria, or bacteroides.

Some anaerobes are etiological agents of important diseases, such as tetanus (*Clostridium tetani*), botulism (*Clostridium botulinum*), cholera (*Vibrio cholera*), salmonellosis and typhoid fever (*Salmonella enterica*), or peptic ulcers (*Helicobacter pylori*). Others, such as the lactic acid fermenters *Lactobacillus* and *Lactococcus*, are involved in the production of food from dairy (yogurt, cheese, kefir, sour cream), vegetables (sauerkraut, olives, pickles), or meat (sausages). Some yeast (*Saccharomyces*) are responsible for bread, beer, and wine production. Finally, the methanogenic archaea carry out the last step of anaerobic degradation of organic matter in the absence of oxygen and, therefore, play a key role in anaerobic wastewater treatment and biomethanization of municipal solid waste processes. It is important to underline that Earth's atmospheric O₂ is of biological origin, and for an extended period of biological evolution, including the period in which the ► [origin of life](#) is suggested, the Earth remained strictly anaerobic. Anaerobes are of astrobiological interest because anaerobic conditions prevail on many planets, for instance, ► [Mars](#).

Chemical Formula

Numerous organic and inorganic electron donors can be utilized by anaerobic phototrophs to fix CO₂, with sulfide being one of the most common electron donors. The chemical formula for anaerobic photosynthesis coupled to hydrogen sulfide oxidation and elemental sulfur formation, one of the most common electron donors for anaerobic phototrophs, is expressed as:

As shown here, oxygen is not produced in this reaction leading to this process being referred to synonymously as “anoxygenic photosynthesis”.

Definition

The process by which anaerobic phototrophic bacteria harvest light energy coupled to fixation of CO₂, without the use of water as an electron donor or the production of oxygen as a by-product.

History

The study of anaerobic photosynthesis stems back to the dawn of microbiology itself with the first documented observation made in 1876 by E. Ray Lankester who noted the formation of red-colored “crusts” in a bacterial enrichment culture from decaying organic matter. The first isolate of a purple anaerobic phototroph, *Rhodospirillum rubrum*, was obtained in 1887 from a Berlin tap water sample in which a mouse had died. In 1907, it was finally demonstrated conclusively that these purple phototrophic bacteria did not produce O₂ (Molisch 1907). The first green anaerobic phototroph, *Chlorobium limicola*, was described in 1906 by Georgii Nadson (1906), which was isolated and characterized by Cornelis van Niel (1932). Since then, huge advances have been made in our understanding of the metabolisms, physiology, lifestyle, and environmental importance of anaerobic phototrophs which is summarized below. A complete timeline of major advances in the study of anoxygenic photosynthesis can be found in Gest and Blankenship (2004)

Overview

Anaerobic photosynthesis is a process by which anaerobic phototrophic bacteria use energy from sunlight to drive the fixation of CO₂. In contrast to oxygenic photosynthesis, which is conducted by organisms such as cyanobacteria and plants, anaerobic photosynthesis does not couple CO₂ fixation to the oxidation of water and therefore does not produce oxygen as a by-product. Instead of using water as an electron donor, these phototrophs utilize numerous inorganic compounds including sulfide, ferrous

iron, hydrogen, or even arsenite (Kulp et al. 2008) and nitrite (Griffin et al. 2007), as well as organic compounds. Several groups of bacteria are capable of conducting anaerobic photosynthesis including green sulfur bacteria (GSB), purple sulfur bacteria (PSB), purple non-sulfur bacteria (PNSB), *Acidobacteria*, *Heliobacteria*, and both red and green filamentous phototrophs such as *Chloroflexi* (Overmann and Garcia-Pichel 2013).

Anaerobic photosynthesis evolved before aerobic photosynthesis and was likely the dominant means of primary production in the Earth's ancient oceans, taking advantage of the anoxic, ferruginous, and sulfidic conditions that dominated for much of Earth's history (reviewed in Camacho et al. 2017). Anaerobic photosynthesis contributed significantly to early biogeochemical cycling, in particular by catalyzing oxidation of Fe (II) which led to the formation of vast deposits of Fe-rich rocks in the ancient oceans (see ► [Photoferrotrophy](#)). Distribution of anaerobic phototrophs became limited as high oxygen concentrations forced them to retreat into anoxic, sunlit niches. They are commonly found today in redox-stratified lakes, waterlogged sands and soils, sulfidic springs, and salt marshes. They are also found in extreme environments such as acidic and alkaline hot springs, salt marshes, soda lakes, and polar environments such as the high Arctic (Madigan 2003).

It is likely that the molecular pathways involved in anaerobic photosynthesis gave rise to aerobic photosynthesis (Blankenship 2010). Aerobic photosynthesis is a more complex molecular process than anaerobic photosynthesis, requiring two connected photosystems (Photosystem I and Photosystem II) to work in tandem. In order to harvest light energy, the chlorophyll-containing reaction center in Photosystem II is excited by light and readily passes an electron down the electron transport chain to a second chlorophyll-containing reaction center in Photosystem I. This second reaction center is excited by light and an electron passed down the second electron transfer chain, ultimately oxidizing NADP⁺ to NADPH. Anaerobic photosynthesis, on the other hand,

requires only one photosynthetic reaction center, where the electron can either end up oxidizing NAD⁺ to create reducing equivalents or return to the reaction center in a process known as “cyclic photophosphorylation.” The Type I reaction center found in the GSB and *Heliobacteria* is structurally similar to Photosystem I found in aerobic phototrophs, whereas the Type II reaction center found mainly in the purple bacteria and filamentous anaerobic phototrophs is similar to Photosystem II. It is therefore considered that the reaction centers in anaerobic phototrophs are the ancestors of Photosystems I and II. It is still debated, however, whether the photosystems were merged in one anaerobic phototroph shortly before the evolution of aerobic photosynthesis or whether ancient anaerobic phototrophs had both photosystems and later specialized to use just one (Allen 2005).

In addition to utilizing different electron transport chains from aerobic phototrophs, anaerobic phototrophs also employ different pigments for harvesting light. Anoxygenic phototrophs use bacteriochlorophylls for this purpose, which are similar to chlorophyll in aerobic photosynthesis. Chlorophyll has peak absorption of light in the red range of the spectrum, whereas bacteriochlorophylls have a maximum absorption in the near infrared. Anaerobic phototrophs, particularly the GSB, also utilize bacteriochlorophylls that are specifically adapted to harvest light at low intensities. This difference in both the wavelength and intensity of light utilized by anaerobic phototrophs can enable them to coexist alongside oxygenic phototrophs in the same environment where they can carve out independent niches based on the wavelength and intensity of light (e.g., de Beer et al. 2017).

To summarize, anaerobic photosynthesis is an ancient metabolism that helped significantly shape the biogeochemical evolution of the Earth, and it provided much of the genetic machinery later adapted for aerobic photosynthesis. Despite being relegated to more specialized environments following the evolution of aerobic photosynthesis, these organisms are still prevalent in many sunlit environments today where they contribute as primary producers and actively

shape the biogeochemical cycling of elements such as sulfur and iron.

Anaximander

Richard Hutchins

Classics, University of Miami, Miami, FL, USA

Keywords

Presocratic philosophy · Ancient cosmology · Multiple worlds · Scientific revolution · Evolution · Naturalism · Infinity

Definition

Anaximander was a Presocratic philosopher from Miletus. Ancient Greek historians of philosophy usually listed him as the second philosopher after Thales. Nonetheless, Anaximander has the greatest claim to be considered the first Greek scientist and to have founded the ancient Greek tradition of naturalistic inquiry into nature.

Overview

Anaximander of Miletus may have been the first Greek scientist. Nonetheless, ancient Greeks typically considered him the second philosopher after Thales. The most secure date for Anaximander comes from the ancient Greek historian of philosophy Diogenes Laertius, who says that Anaximander was 64 years old in 547 BCE. Anaximander is said to have drawn the first map of the world, perhaps created a spherical model of the heavens, and is credited with introducing the gnomon. A gnomon is a stick set vertically in the ground to measure the sun's shadow and, thus, its altitude, paving the way for complex astronomical observations of the sun's movements. Anaximander is most famous for his claim that the starting point and original material of the universe is the "indefinite" or "boundless," i.e., the *apeiron*, in ancient Greek. By *apeiron*, Anaximander meant something that can be delimited neither internally nor externally, hence, the "indefinite" or "boundless." The *apeiron* may refer to the boundless beyond from which all worlds arose. Aristotle took Anaximander to mean an indeterminate substance out of which the opposite principles of hot and cold emerged. Either way, Anaximander's silence on the specific details of the *apeiron* seems to evince a rational caution about the origin of the universe (Schofield 2008).

As the material starting point, or *arche*, of the cosmos, the *apeiron* was in constant motion before the beginning of the universe (Hippolytus *Refutation of all Heresies* 1.6.2). Aristotle attributes mental and god-like qualities to it in his report that the *apeiron* "steers all" and is "indestructible" (*Physics* 203b7ff). Anaximander seems to have believed that the cosmos began when two fundamental material principles break out of the *apeiron*: the hot and the cold. Originally, the hot formed itself into a fiery sphere that encased the cold, growing around the earth "like the bark around a tree" (Pseudo-Plutarch = Clement *Stromata* 2), eventually becoming the celestial bodies. The cold became the sublunary air, or mist, and earth. It is through the reciprocal interactions of the hot and the cold that the multiple worlds become increasingly differentiated. Our world, Anaximander thought, was originally a

watery place that gradually dried up under the heat of the sun.

The only direct quotation we have from Anaximander seems to allude to the increasing differentiation of worlds through the reciprocal interactions of the hot and the cold. This sole fragment of Anaximander comes to us from the sixth-century Neoplatonist philosopher Simplicius (*Commentary on Aristotle's Physics* 24.13–21 = Laks & Most D6). Since the extent of the fragment is disputed by scholars, the full quotation from Simplicius is reproduced here, with Anaximander's likely words in bold: "He says that the *arche* [starting-point of the cosmos] is neither water nor any of the other things called elements, but some other nature, the *apeiron*, out of which come to be all the heavens (or "skies:" *ouranoi*) and the worlds (*kosmoi*) in them. The things that are perish into the things from which they come to be, **according to necessity. For they pay the penalty and retribution to each other for their injustice according to the order of time**, as he says in very poetical language." Anaximander not only posits a starting point, or *arche*, for the cosmos but describes the cosmos as behaving in an orderly, law-like way that is knowable by humans. The causes of the world are not random or dependent upon the whims of deities but follow a stable reciprocal process within a developing cosmos. Anaximander also may have anticipated the "principle of sufficient reason" in his claim that the earth is not supported by anything, but floats in space with its position fixed (Kahn 1994). Aristotle reports (*On the Heavens* 2.13295b11–16) that Anaximander said: "the earth stays fixed because of equality (*homoioteta*). For it is no more fitting for what is established at the center and is equally far from the extremes to move up or down or sideways. And it is impossible for it to move in opposite direction at the same time. Therefore, by necessity (*ex anankes*) it stays fixed."

Anaximander may have held proto-evolutionary views about the origins of species, including humans. While no ancient author thought that one species evolves into another (Campbell 2014), Anaximander is cited by the late second-century ACE bishop of Rome Hippolytus (*Refutation of All Heresies* 1.6.6) as saying that "living creatures

came into being from moisture evaporated by the sun. Man was originally similar to another creature—that is, to a fish.” But other reports of Anaximander’s thought suggest that he was not so much addressing human evolution as trying to solve the problem of how the first human infants survived before there were human parents. As the late antique author Pseudo-Plutarch reports (*Stromata* 2): “He [Anaximander] says that in the beginning man was born from creatures of a different kind; because other creatures soon become self-supporting, but man alone needs prolonged nursing.” The Roman grammarian Censorinus (*Censorinus. The Birthday Book* 4.7) attributes to Anaximander the idea that human infants were initially carried inside fish as if in embryos, until puberty when the self-supporting humans could step out onto dry land: “Anaximander of Miletus thought that when the water and earth were heated, there arose either fish or creatures very similar to fish (*piscibus simillima animalia*); in these human beings developed and were retained within as embryos (*fetus*) until puberty; then at last the fish-like creatures burst and men and women who were already able to nourish themselves stepped forth.” Thus, Anaximander may not have been claiming that humans evolved from a fish-like ancestor, but that the first human infants survived the originally watery world by living inside fish for nourishment and protection. This accords with what Anaximander is reported to have thought about other animal infants, as stated by first–second-century philosopher Aëtius (5.19.4 = Laks & Most D38): “Anaximander says that the first animals were born in moisture, enclosed in thorny barks. When their age advanced, they came out onto the drier part, and when their bark burst open they changed their mode of life (*metabionai*) in a short time.” Here, it is important to emphasize how Anaximander’s cosmological and biological hypotheses reinforce each other. There seems to be an analogy between how the principles of hot and cold broke off from the *apeiron*, how animals burst out of their bark-like encasings after the watery earth dried out, and how humans burst out of fish-like animals before setting foot on dry land. While Anaximander does not seem to think that one animal can evolve from another, he does seem to think that new forms and ways of life appear or develop by breaking out of old ones,

whether in the heavens or on earth. Thus, while obscure, Anaximander seems to have used a common structure of thought for his cosmology and biology: at first one kind of stuff encases another, then that inner material breaks out of its encasement so that new forms can appear.

Anaximander’s claim to be the first scientist rests on several innovations. Anaximander was the first to compose a book in prose about the natural world, called the *Peri phuseos*, or “On Nature.” In this book, he presented an all-embracing vision of the natural world, ordered by laws, and based on the stable interactions of the opposing principles of the hot and the cold. This laid the groundwork for a tradition of naturalistic inquiry in ancient Greece, *phusiologia*, that could be seen as forming the basis for all scientific revolutions to come. Anaximander was also the first geographer and biologist. Anaximander introduced important conceptual tools into the study of nature, using the concepts of “law” and “necessity” to rationally explain the observable world. He also held an entirely new view of the earth as floating, unsupported, in space. As theoretical physicist Carlo Rovelli has passionately argued, in his rebellion against the Greek mythological worldview, Anaximander came to realize that “scientific revolutions are possible: in order for us to understand the world, we must be aware that our world-view may be mistaken and we can redraw it (Rovelli 2011).”

Angular Diameter

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The angular diameter of a celestial object, seen from Earth, is the apparent diameter measured in angular units. Planets in the solar system have typical angular diameters between a few arcsec up to 50 arcsec (0.25 m-radians).

Keywords

Rotating body

Definition

In mechanics, angular momentum is the vector cross product between the position vector and the momentum vector of a point mass system. This definition can be extended to a solid by summation.

Overview

The movement of a point mass m is defined by its position r and its velocity v . These quantities are **vectors** relative to some reference system. This movement splits into two parts: a movement of translation and a movement of rotation. The amount of movement is measured by the linear momentum (impulsion) $p = mv$ (for simple cases), which is a conserved quantity for a translation invariant system. The amount of rotation is measured by the angular momentum $L = r \times p$, which is a conserved quantity for a rotation invariant system. Note that the vector cross product $a \times b = ab \sin \theta n$, where θ is the smaller angle between a and b ($0^\circ \leq \theta \leq 180^\circ$), a and b are the magnitudes of vectors a and b , and n is a unit vector perpendicular to the plane containing a and b in the direction given by the right-hand rule.

Variations of velocity are produced by forces, in accordance with Newton's second law of dynamics. If forces that apply on the point are aligned with the position vector r , they are called central, the system is invariant under rotation, and its angular momentum is conserved. As ► [gravitation](#) is a central force, this conservation occurs frequently in astronomy.

When the system is extended, such as a solid planet described by a distribution of points whose relative distances are fixed, the total angular momentum is the sum of the contributions of all these points. In this case, it is distributed between the spin of the planet itself and the angular momentum of its orbit.

The conservation of angular momentum of celestial bodies is a fundamental tool for analyzing their properties. For example:

- In a two-body problem (see ► [“Gravitation”](#)), if one of the two bodies is much heavier than the other, the conservation of angular momentum implies Kepler's third law (see ► [“Orbital Resonance”](#)) and allows us to obtain the value of the large mass from observations of the period and of the semimajor axis of the small mass.
- If a planet is found to rotate slower than expected, one can suspect that this planet is accompanied by a satellite, because the total angular momentum is shared between the planet and its satellite in order to be conserved.
- The tidal torque the Moon exerts on the Earth implies a slowing down of the rotation rate of the Earth (at about 42 ns/day). As a consequence and because the total angular momentum of the whole system is conserved, the distance between the Earth and Moon gradually increases by 4.5 cm/year.

Anion

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

An anion is an atom or molecule that has gained an electron (e.g., CN^- , OH^- , C_4H^-). Neutral molecules with large electron affinities (EAs) can attach an electron in a variety of chemical reactions, such as electron photo attachment. Long carbon-chain molecules have large EA values, and C_6H^- was the first anion discovered in the interstellar medium in 2006.

Annefrank

Stefano Mottola
German Aerospace Center (DLR), Institute of
Planetary Research, Berlin, Germany

Definition

(5535) Annefrank is a small S-class, main-belt asteroid named after the Jewish victim of Nazi persecution famous for her diary. The Discovery spacecraft Stardust encountered the asteroid on November 2, 2002 on its route to comet Wild 2. During the fast flyby, the space probe recorded an image sequence lasting about 15 min and consisting of over 70 images. Although the

imagery had a comparatively low resolution in the range of 300–185 km/pixel and covered only about 40% of the surface, the sequence revealed a body with approximate dimensions of $6.6 \times 5.0 \times 3.4$ km and an angular appearance, reminiscent of a contact binary or of a re-accumulated pile of fragments.

Anorthosite

Nicholas Arndt
ISterre, University Grenoble Alpes, Grenoble,
France

Definition

Anorthosite is an igneous intrusive rock. It is light colored (leucocratic) and has a medium to coarse grain size (phaneritic). It is mainly composed of plagioclase (andesine, labradorite, and bytownite), minor pyroxene, olivine, and iron-titanium oxides (ilmenite and magnetite). Proterozoic anorthosite forms large massifs associated with granitoids (North America, Scandinavia). Archean coarse-grained (megacrystic) anorthosite occurs in intrusions (dikes and sills) and flows of basaltic composition. Anorthosite is a common constituent of the lighter surfaces of the Moon called lunar highlands or terrae. Formation of anorthosite requires the concentration of plagioclase from mafic magma by flotation in a magma ocean (as is proposed to have occurred on the Moon), ascent of plagioclase-rich mushes, or low-pressure crystallization in magma chambers.

[Antarctic continent](#)

Definition

Antarctica is the ice-covered continent located in the Southern Hemisphere of the Earth. It is situated almost entirely south of the Antarctic Circle and is surrounded by the Southern Ocean.

Because it is the driest and coldest place on Earth, its natural surface environments have been considered to be a good analogue site of the Mars Northern Plains.

History

Since Aristotle, it was suspected that an important landmass was situated at the South Pole (*Terra Australis Incognita*), yet the continent of Antarctica was discovered only in 1820 by a Russian expedition onboard the *Vostok* and *Mirny* vessels and led by Fabian Gottlieb von Bellingshausen and Mikhail Lazarev. They discovered an ice shelf at Princess Martha Coast that later became known as the Fimbul Ice Shelf. Several land sightings followed in years, but only in 1841 the first expedition to the interior of Antarctica was organized and conducted by James Clark Ross, discovering mountains as the Erebus volcano.

With the progressive conquest of the Antarctica by numerous expeditions in the following century and the establishment of scientific bases by several countries, the Antarctica continent was deeply investigated, and scientific experiences settled. In 1903, US explorer Robert Scott discovered the dry valleys around the future McMurdo polar station. These valleys are the driest places in Antarctica, not covered by the ice sheets and presently showing morphological features identical to Martian Northern Plains. One turning point for future astrobiological investigation was the discovery of the subglacial Lake Vostok in the late 1960s, a potential niche of deep extreme biosphere.

Overview

Antarctica, the coldest and driest continent on Earth, is technically considered a desert, with only 166 mm per year of average precipitation. Antarctica also recorded the coldest temperature on Earth measured so far, of $-89.2\text{ }^{\circ}\text{C}$, at the

Vostok station. Ninety-eight percent of Antarctica's 14 million km^2 surface area is covered by a 1.6 km thick ice sheet, corresponding to 90% of the world's ice. It has been covered by ice for the past 15 Ma. About 380 subglacial lakes lie at the base of the continental ice sheet, the best-known being Lake Vostok. Lake Vostok has remained isolated for 14 million years, making it a valuable analogue for exploring deep biosphere niches. Antarctica's ice surface shares similarities with those of Jupiter's moon Europa and Mars. Further, the possible presence of subglacial oceans on the Saturn's moon Enceladus has sparked renewed interest in studying subglacial lakes such as Vostok Lake, for testing the possibility that life forms could have developed or survived on this far moon.

Antarctica has been for a long time a privileged natural analogue terrain for studying morphological and weathering processes shaping the Mars surface, for testing instrumentation and field exploration procedures, and training astronauts for routine space missions and future-manned Mars missions. Particularly, ice-free Antarctica McMurdo *Dry Valleys* reflect surface conditions similar to those of the Mars surface. Dry valleys are located mainly in the Victoria Land west of McMurdo Sound. Dry valleys are so named because of their extremely low humidity and their lack of snow and ice cover. Their surfaces are covered by loose gravel and show ice-wedge polygonal-patterned ground. Polygonal-patterned ground is a geometric landform with characteristic honeycomb patterns surrounded by ice crests that develop in periglacial regions which experience intense freezing and thawing cycles. High Resolution Imaging Science Experiment (HiRISE) camera on NASA's Mars Reconnaissance Orbiter has clearly shown the same patterns on high latitudes of Mars and at the bottom of some Mars crater. Antarctica's Dry Valleys and Mars' midlatitudes soil formation histories share similarities, particularly involving slow processes of sublimation and poleward migration of water (Wentworth et al. 2005). Radiation-resistant bacteria from

Antarctic Dry Valleys were also isolated and studied to test whether extremophiles could survive large doses of UV-radiation in hostile environments such as Mars' surface (Musilova et al. 2015).

Antarctica's permafrost hard surfaces are a privileged site of several Mars analogue missions, because the soils share physical similarities with that of Mars. One of the most recent missions took place in the Marambio Island, Western Antarctic Peninsula, where field exploration, sample collection, instrument deployment, and spacesuit testing were carried out on a Mars-like rocky, permafrost-rich landscape (Rask et al. 2012). NASA is now testing a Buoyant Rover for Under-Ice Exploration (BRUIE), developed for underwater exploration in extraterrestrial, icy worlds such as Enceladus.

Definition

The 3.465 Ga Apex Chert is a chert unit within the Apex Basalt in the Warrawoona Group, which is part of the oldest greenstone sequence in the Pilbara granite-greenstone terrain. The Apex Basalt is stratigraphically below the Strelley Pool Chert, a unit known for hosting the oldest ► [stromatolite](#) on Earth. In the Apex Chert, small carbonaceous filaments with $\delta^{13}\text{C}$ as low as -22.5‰ to -25‰ were reported to represent evidence for ► [cyanobacteria](#) able to recycle inorganic carbon through ► [RubisCO](#). The Apex Chert microfossils occur in rounded grains of microcrystalline silica, which have been interpreted as clasts in a conglomerate deposited in a wave-washed beach or a stream mouth, an ideal environment for cyanobacteria. Subsequent work suggested that the chert was deposited from hydrothermal fluids with a temperature higher than 250 °C and that the microtextures may result from abiotic processes under those temperatures. If biogenic, microfossils could represent remains of thermophile chemotrophs living close to hydrothermal vents.

Synonyms

Apex chert; Apex basalt formation; Schopf locality; Earth's oldest microfossils

Definition

The Apex Chert is a lenticular and bedded, laminated, microcrystalline silica (SiO₂) deposit interlayered with and crosscutting submarine lavas of the Apex Basalt Formation, Pilbara Craton, Western Australia. The Apex Basalt Formation, Salgash Subgroup of the Warrawoona Group dates at 3465–3458 Ma. The origin of the chert is disputed. The rivaling interpretations: diagenetic silicification (chertification) of clastic or carbonate sedimentary and volcano-sedimentary rocks *versus* primary silica deposition on the ocean floor or hydrothermal chert intrusion and replacement, do not necessarily contradict each other. Varying chert generations may coexist where black chert dikes and lenses crosscut dark gray and whitish stratiform cherts and interlayered volcanics of the Apex Formation (Marshall et al. 2012). Carbonaceous filaments found in the Apex Chert beds, Chinaman Creek near Marble Bar, were interpreted as world's oldest fossils and as evidence for the antiquity of life on Earth (Schopf 1993). The name “Schopf locality” was given to this outcrop after J. William (Bill)

Schopf, an American paleontologist and paleobiologist of the University of California, Los Angeles, who found and described these microfossils.

History

Because of geological recycling of rocks and their progressive destruction by diagenesis, metamorphism, and tectonic forces, Precambrian fossils rarely survive postdepositional processes. Further, they are difficult to trace for their evolutionary simplicity and microscopic sizes. Already Charles Darwin has desperately missed the fossil record of the pre-Cambrian. No fossils older than Cambrian advanced multicellular organisms were known at his time. They must have evolved from simpler Precambrian life forms of which, however, no vestige was available. With the development of microscopic techniques and geochemical methods, an increasing number of scientific reports on putative Archean microfossils, started to emerge in the 1980s (e.g., Awramik et al. 1983; Buick 1984). Schopf and Packer (1987) published a report on 3.5 billion years old microfossils from the Warrawoona Group in Western Australia, followed by more detailed descriptions of these then oldest fossil evidence of life on Earth (Schopf 1993).

Twenty years later, an international group of researchers around the late Martin Brasier, paleontologist at Oxford University, questioned Schopf's (1993) interpretation, based on renewed microscopy of the same fossils and discredited them as “secondary artefacts formed from amorphous graphite” (Brasier et al. 2002). These claims triggered a turmoil discussion on the quality of all reports of Archean life remains and avowed that life might have developed only in the Proterozoic (Brasier et al. 2004), a view, however, which did not last for long.

Overview

Schopf (1993) reported 11 morphological taxa of filamentous and coccoidal prokaryotic

microfossils found in the bedded Apex Chert. He interpreted the host rock as chertified sedimentary beds containing kerogenous (carbonaceous) filaments, up to several tens of micrometers long and 1–20 μm wide. Most filaments displayed typical cyanobacteria-like septation and terminal cells of varying morphology (Fig. 1). The morphology of the filaments and their organic carbon isotopic

composition ($\delta^{13}\text{C}$ -22‰ to -26‰ vs. PDB, whole rock measurements), and the sedimentary environment interpreted as shallow marine, strongly suggested that they represent Earth's oldest microfossils, some of strong cyanobacterial affinity. The hypothesis of cyanobacterial life 3.5 billion years ago implied, for uniformitarianism, that oxygenic photosynthesis has acted very early

Apex Chert, Microfossils, Fig. 1 Apex Chert, Microfossils, Fig. 1 Microfossils from the early Archean Apex Chert of Australia (From Schopf 1993). Microfossils (A–J, holotypes) with interpretative drawings. All at a magnification

as shown in (A). (a–e) *Primaevifilum amoenum*; (f–j) *Primaevifilum conicoterminatum* (with conical terminal cells)

in the Earth's history and that life was already well advanced one billion years after the Earth's formation.

After Brasier et al.'s (2002, 2004) alarming claims of hydrothermal artefact origin of Schopf's microfossils, the turbulent debate on the Apex Chert and its putative microfossils greatly contributed to rising general interest in the origin and evolution of life. In the course of this debate our understanding of abiotic and biotic, evolutionary and taphonomic processes (by which organisms become fossilized) was vastly improved and new investigation methods and definitions of unambiguous biosignatures were developed. Schopf's microfossils are today largely regarded as genuine *bona fide* remains of Archean life, doubting reviews are, however, still valid (e.g., Javaux 2019; Lepot 2020). Nevertheless, Archean microbialites and stromatolites found in 3.7 Ga – 2.5 Ga rocks (Ueno et al. 2001; Kazmierczak and Altermann 2002; Allwood et al. 2006; Nutman et al. 2016; Homann et al. 2018) are abundant. Brasier et al. (2015) reported Archean microfossils from the 3.43 Ga Strelley Pool Chert (still disputing Schopf's 1993 findings). Up to date (2021), about a dozen of Archean, low metamorphosed stratigraphic formations are reported to contain microbialites, stromatolites, and microfossils of Archean age. Among such reports are findings from the Kaapvaal Craton and the Barberton Greenstone Belt (South Africa), from Pilbara Craton (Western Australia), Zimbabwe Craton and the Belingwe Greenstone Belt, Isua (Greenland), various occurrences in India (but mainly Singhbhum Craton), or from North America (e.g., Abitibi Greenstone Belt or the Slave Craton). Almost all of these reports are doubted one way or another and even the depositional environments are being controversially debated (e.g., Sugitani et al. 2009; Retallack et al. 2016; Sugitani et al. 2018, and many more).

Basic Methodology

The debate on the veracity of Schopf's microfossils provoked a radical change in the investigation

methods of putative fossils – initially based on optical and electron microscopic morphological assessment, and supported by whole rock $\delta^{13}\text{C}$ measurements. Micro- and nano-geochemical, mineralogical, and isotopic analytical methods were introduced. Laser Raman spectroscopy and H/C and N/C ratios measured on particulate kerogens isolated from bulk samples; atomic force microscopy (AFM), focused ion beam (FIB) techniques, and nano-SIMS analytical measurements were applied directly on filaments and coccoids as standard techniques, evidencing the organic or inorganic nature of the investigated materials (for further reading, comp. Schopf 2004; Schopf and Bottjer 2009). Optical microscopy on 30–60 μm thick petrographic rock sections in transmitted light is, however, still the basis of all such investigations for it allows to judge the fossil remnants in their embedding rock context.

Key Research Findings

Geology of the Schopf Locality

The Apex Chert is an informal unit within the 4 km-thick Apex Basalt Formation. It consists of greenschist facies metamorphosed basalts, komatiitic basalts; serpentized peridotites; tuffs and minor felsic volcanoclastic rocks; and locally developed chert dikes and stratiform cherts, intruded by dolerite sills and dikes at different levels. These rocks form part of the Marble Bar greenstone belt with several occurrences of cherts, stromatolites, and microfossil reports. The most important of such manifestations are the Dresser Formation chert (3490 Ma, stromatolites and microfossils), the Mc Phee Formation (ca. 3477 Ma) Awramik micro-fossiliferous locality (after Stanley Awramik et al. 1983), the Marble Bar Chert, and above the Apex Chert, the Strelley Pool Chert with stromatolites and microfossils, and finally the Wyman Formation stromatolitic chert (ca. 3315 Ma).

The “Schopf locality” (Schopf and Packer 1987; Schopf 1993), north of Marble Bar, with an assigned age of 3465 ± 5 Ma, displays white, gray- and black-layered chert, of up to 10 m thick,

interbedded with felsic tuff, which contains sills of massive black silica. The bedded deposits overlie a swarm of black silica veins radiating side-wards into sedimentary layers and extending up to 750 m down stratigraphy into meta-basalts, but not penetrating above the bedded chert horizon, cut by an unconformity. The veins migrate side-wards into sedimentary layers replacing them with silica.

Remapping and detailed petrology and mineralogy of the Apex Basalt Formation and the Apex Chert (Brasier et al. 2002; Van Kranendonk and Pirajno 2004) revealed that the Apex Chert is largely a breccia infilling of multiple generations of metalliferous hydrothermal veins which cross-cut pillow basalts and feed into, and are continuous with the overlying stratiform-bedded chert unit of the Apex Basalt Formation. The bedded chert of the Schopf microfossil locality is one of the stratigraphically lowest of five bedded chert units within the pillowed Apex Basalt, controversially within a black chert vein radiating from a bedded chert.

Microfossils at the Schopf Locality

The fossiliferous specimen deposited by Schopf at the Natural History Museum, London, show bedded structure and brownish color, implying that they come from a bedded part of the section. Microfossils were discovered in rounded grains of microcrystalline silica interpreted by Schopf (1993, 1999b) as conglomerate clasts deposited in a wave-washed beach or a stream mouth, an ideal environment for cyanobacteria. Fragments of stromatolites provide evidence that at least part of the clasts is of sedimentary origin. Schopf (1993) observed hundreds of bacterial filaments, up to few hundreds μm long and 20 μm wide, some resembling rather cyanobacteria through their size, septate division and terminal cell morphology (Fig. 1). Next to the filaments, hundreds of solitary unicell-like spheroidal structures resembling coccoidal microfossils were identified. Based on morphology, Schopf and Packer (1987) and Schopf (1993) recognized 11 morphotypes of putative microfossils in the Apex Chert, as listed below:

1. Narrow unbranched septate prokaryotic filaments *incertae sedis* cf. bacteria? (Archaeotrichion septatum)
2. Narrow unbranched septate prokaryotic filaments *incertae sedis* cf. bacteria? (Eoleptonema apex)
3. Narrow unbranched septate prokaryotic filaments *incertae sedis* cf. bacteria? or cyanobacteria? (Primaevifilum minutum)
4. Narrow unbranched septate prokaryotic filaments *incertae sedis* cf. bacteria? or cyanobacteria? (Primaevifilum delicatulum)
5. Intermediate-diameter unbranched septate prokaryotic filaments *incertae sedis* cf. cyanobacteria? (Primaevifilum amoenum)
6. Intermediate-diameter unbranched septate prokaryotic filaments having disk-shaped medial cells *incertae sedis* cf. cyanobacteria? (Archaeoscillatorioopsis disciformis)
7. Broad unbranched septate prokaryotic filaments having conical end cells *incertae sedis* cf. cyanobacteria? (Primaevifilum conicoterminatum)
8. Broad unbranched septate prokaryotic filaments having equant medial cells *incertae sedis* cf. cyanobacteria? (Primaevifilum laticellulosum)
9. Broad unbranched septate prokaryotic filaments *incertae sedis* cf. cyanobacteria? (Archaeoscillatorioopsis grandis)
10. Broad unbranched markedly tapering septate prokaryotic filaments *incertae sedis* cf. cyanobacteria? (Primaevifilum attenuatum)
11. Broad unbranched septate prokaryotic filaments having hemispheroidal end cells *incertae sedis* cf. cyanobacteria? (Archaeoscillatorioopsis maxima)

The Debate

The debate on Schopf's (1993) findings included claims that the filaments are branching, unlike prokaryotic filaments and do not contain carbon. The discussion climaxed in misconceptions of the "null hypothesis" that no prove of life older than ca. 2700 Ma can be yet accepted (Brasier et al.

2004, 2006). It was suggested that the preserved morphological variation indicates biological behavior and fulfills the requirements for microfossil recognition (Buick 1990), although some lack of assessment of geological context of the Apex microfossil assemblage together with biological, diagenetic, and metamorphic degradation may cast doubts on the applied taxonomy (Altermann 2005). Thermal alteration may have caused taphonomic changes in cyanobacterial microfossils, resulting in the present form of microfossil preservation in the Apex Chert (Kazmierczak and Kremer 2002). Claims of branching of the filaments or of incomplete, selective photomontages of the microstructures, mimicking a biological appearance (Brasier et al. 2002, 2004) resulted from misinterpretation of auto-montages of photographs taken at different depths of focus and superimposed on each other (Altermann 2005 and Fig. 2). At reexamination by three-dimensional confocal laser scanning microscopy and Raman imagery, the Apex Chert was found to contain cellular-preserved kerogenous microfossil remains, revealing advanced biostratinomic (i.e., after an organism dies but before its final burial) to metamorphic, taphonomic changes (Schopf and Kudryavtsev 2009).

Scanning electron microscopy (SEM) showed the presence of metals (Ni, Cu, Zn, Sn), sulfides, barite, jarosite, alunite, phyllosilicates, and Fe oxides in the embedding cherts, suggesting a high-temperature hydrothermal environment where microbial life could hardly have survived (Brasier et al. 2002). But early microbes could have been chemo-autolithotroph thermophiles as controversially discussed (Brasier et al. 2006; Sugitani et al. 2007; Wacey et al. 2018) or simply extinguished and fossilized under hydrothermal conditions. An acid-sulfate epithermal environment of alteration, syn- or post-genetic with the precipitation of the chert, has been suggested by van Kranendonk and Pirajno (2004). The abundance of sulfate and lack of argillitic alteration indicate depositional temperatures up to 350 °C. Subsequently, Pinti et al. (2009) showed that medium-low temperature weathering processes could explain the mineralogy of the Apex Chert

so that high-temperature hydrothermal fluid-rock interactions are not required. Alternatively, the metal rich fluids might have passed at a much later time through these rocks.

Contradicting observations and interpretations invigorated the debate on the biogenicity of the carbonaceous filaments and their putative inclusion in the phylum cyanobacteria. Laser-Raman imagery of carbonaceous filaments (Schopf et al. 2002; Brasier et al. 2002) and of disseminated carbonaceous (kerogenous) matter in the Apex Chert gave controversial results. Schopf et al. (2002) interpreted the carbon as of biological origin. Brasier et al. (2002) proposed that it rather could be amorphous carbon reorganized in the form of filamentous strains after devitrification processes of the chert veins. De Gregorio and Sharp (2006) suggested that the carbonaceous material is similar in structure to microfossil kerogen, but may also be produced abiotically via Fischer-Tropsch-type (FTT) synthesis reactions, in an ancient hydrothermal vent. The results of 3-D laser scanning and Raman microscopy (Schopf and Kudryavtsev 2009) were questioned by Marshall et al. (2012) and Sforza et al. (2014) who investigated the Apex Chert material but not the original specimen described by Schopf (1993). In subsequent investigations, Wacey et al. (2016, 2019) have collected similar material from the same Apex Chert locality and used high spatial resolution electron microscopy to decode the morphology, chemistry, and taphonomy of the filamentous structures and concluded that they formed during fluid flow by hydration, heating, and exfoliation of potassic mica flakes within an active hydrothermal system.

The carbon isotopic composition of the rocks and microfossils is also controversial. The *in situ*, on single microfossil, measured $\delta^{13}\text{C}$ values from -27‰ to -34‰ versus PDB could be related to photosynthesis ($\delta^{13}\text{C} = -25\text{‰} - -10\text{‰}$; Schopf et al. 2002), methanogenesis (Brasier et al. 2002), or abiotic FTT reactions (e.g., McCollom and Seewald 2006). Buick (1984) suggested that carbonaceous filaments in the silica swarm dykes of the North Pole and Marble Bar, including Apex Chert, were contaminants introduced in the microfracturing of the silica veins during tectonic uplift

Apex Chert, Microfossils, Fig. 2 The same specimen of *Archaeosclerotriopsis disciformis* filament photographed from the original material deposited by Schopf at the Natural History Museum, London. Upper left, as depicted by Schopf (1993), and upper right, as shown by Brasier et al. (2002); the difference created the impression that Schopf (1993) has manipulated the microphotographs in reality showing a branching and therefore impossibly cyanobacterial filament. The following lower micrographs show the same filament at different depth of focus within the several tens of μm thick petrographic thin section (from left to right and downwards). It becomes clear that Schopf

(1993) has shown only one filament located closer to the surface of the section, while Brasier et al. (2002) have shown a sandwich photograph, including all depth of focus and exhibiting two filaments coincidentally superimposed one above the other within the thickness of the section. Lowermost series of six pictures show two neighbouring filaments of *Primaevifilum amoenum* located at different depth of focus. Viewed from a different angle in a sandwiched series of photographs taken at varying focus levels, they would appear as an “X”, or as branching, or crossing each other (Photograph by W. Altermann in M. Brasier’s lab, 2003)

of the region 2750 myr ago. Schopf et al. (2018) have used *in situ* – on microfossil, secondary ion mass spectroscopy (SIMS) to demonstrate that the

$\delta^{13}\text{C}$ measurements of the Apex taxa are consistent with extant phototrophic bacteria, with non-bacterial methane-producing Archaea and

Apex Chert, Microfossils, Fig. 3 Stromatolitic clast within the microfossiliferous samples deposited by Schopf at the Natural History Museum, London, exhibiting microbial lamination, pyrite grains, and dark organic matter. The

clast is cut by two parallel silica veinlets with pyrite enrichment (Photograph by W. Altermann in M. Brasier's lab, 2003)

with methane-metabolizing γ -proteobacteria, depending on the measured values and morphotypes. They concluded a cellular preservation and basal position (Archaea) in rRNA phylogenies of these microorganisms. On the other hand, Pinti et al. (2009) observed branched microstructures suggesting postdepositional colonization of microcracks and fissures by microbes. However, Schopf's kerogenous microfossils are embedded in sedimentary clasts deposited within the Apex Chert. Some clasts contain stromatolitic laminae and relict carbonate minerals and therefore must have been silicified during early diagenesis at their source of origin (Fig. 3). The hydrothermal chert distinctly differs from these clasts. However, in some places, hydrothermal recrystallization strongly affects the clasts and they become almost non-discernible from the hydrothermal chert matrix. The clasts must be older than the hydrothermal dikes (Altermann and Kazmierczak 2003; Altermann 2007). The Apex Chert has been affected by several hydrothermal and supergene episodes of alteration.

Whether the carbonaceous filaments of J. William Schopf are genuine ancient, fossilized prokaryotes (Schopf 1993; Kazmierczak and Kremer 2002; Altermann 2005), later biological contamination (Buick 1984; Pinti et al. 2009), or abiotic products (Brasier et al. 2002, 2004), this rock is still one of the most fascinating challenges

in Archean paleobiology and astrobiology. Each time Schopf reinforced his arguments for microfossils, introducing new data and new investigation techniques he was again challenged by his opponents (e.g., Schopf and Kudryavtsev 2012, 2013; Schopf et al. 2018; Pinti et al. 2013; De Gregorio and Sharp 2006; Sforza et al. 2014, Wacey et al. 2016, 2019; Lepot 2020). The critical point in views opposing the microfossil interpretation is that most of these investigations were not made on the original specimen described and deposited in the Natural History Museum, London, by Schopf (1993), but on rocks collected years later, in the same outcrops but not exactly the same location and on geochemical investigations not available in the 1980s–1990s. Nims et al. (2021) have shown that chemical artifacts mimicking microfossils are abundant in Archean cherts and have a much higher chance of preservation than genuine microfossils. This is not new and although unequivocally true, such findings do not contradict the overwhelming evidence for Archean life since ca. 3.7 Ga and Schopf's findings and interpretations. While new interpretations and debates are welcome in science, legitimate allegation of misinterpretation require investigations of the same samples, from exactly the same place and with exactly the same content. Whether they are right or wrong, they can add to the knowledge, asking and answering important questions.

Applications

Most of all the techniques available for determining the biogenicity and syngenicity of Archean traces of life have been tested on Apex Chert. Several among them were specifically developed to resolve the dilemma of Schopf's microfossils. This rock represents thus the best challenge for determining the reality of very ancient traces of life and developing successful methodologies and strategies of search for extraterrestrial life. With the development of new techniques and their automatic, remote-controlled extraterrestrial application, problems in understanding the contents of an ancient rock on nanometer scale (e.g., Kempe et al. 2005) will grow and fierce controversies on possible alien fossil remains (Schopf 1999a).

Future Directions

The uniqueness of Archean microfossils constrains the use of destructive methods for determining the environmental context of deposition of this chert unit and the reality of these microfossils. New nondestructive techniques such as NanoSIMS imagery of microfossils (e.g., Oehler et al. 2009; Schopf et al. 2018) or a combination of analytical techniques could be useful for determining whether the chemical structure of such putative microfossils is consistent with a biological origin (e.g., Derenne et al. 2008). Detailed investigation of the varying generations of cherts by, for example, fluid inclusion micro-geothermobarometry and decrepitation geochemistry of such fluid inclusions would certainly add tremendously to understanding of the history of the Apex Chert.

Apolar Molecule

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

[Nonpolar molecule](#)

Definition

In interstellar chemistry, apolar molecules are molecules lacking a permanent electric dipole moment. The lack of a dipole moment results from the symmetry of the charge density distribution in the molecule. Such molecules have no pure rotational transitions; hence, in the gas phase, they must be observed via their vibrational or electronic transitions.

Definition

The Apollo missions were the heart of NASA's manned Lunar Landing Program that took place between 1969 and 1972 with 6 successful landings of 12 astronauts on the Moon.

History

On July 20, 1969, the astronauts N. A. Armstrong and E. E. Aldrin were the first humans to set foot on the Moon. Herewith, NASA had reached the ambitious goal of its manned Lunar Landing Program. It was made possible by the strong commitment of the United States to manned lunar exploration with President J. F. Kennedy's announcement in 1961 of sending an American safely to the Moon before the end of the decade and at same time the progress in the

technical capabilities of space transportation. The Apollo program ultimately placed 12 men on the lunar surface. In 1972, with Apollo 16 and 17, the era of human exploration beyond Earth's orbit was terminated and so far it has not been resumed.

Overview

The Apollo missions to the Moon were performed between 1968 and 1972 (Table 1).

The Apollo missions were the first and so far only human space missions beyond Earth's orbit. They provided in-depth knowledge of the geology of the Moon (Schaber 2005) and biomedical data on human health issues during space flight (Johnston et al. 1975). Biological responses to the parameters of outer space were studied in the following experiments:

- ► [Biostack](#) experiments on board of the Apollo 16 and 17 Command Module on the responses of a variety of biological systems in resting state to the heavy ion component of cosmic rays (Bücker and Horneck 1975)
- ALFMED experiment during the Apollo 16 and 17 mission that demonstrated that the light flash phenomenon observed by the crew members after dark adaptation was attributed to the passage of cosmic ray ions through the retina of the eye (Johnston et al. 1975; Benton et al. 1977).
- BIOCORE experiment during the Apollo 17 mission that studied brain effects in pocket mice caused by the passage of single heavy ions (► [HZE particles](#)) of cosmic radiation (Klein 1981)
- MEED during the Apollo 16 mission that studied the effects of space vacuum and solar UV radiation on different functions of microorganisms (Taylor 1974)

The radiobiological experiments performed during the Apollo missions are the only ones that studied the biological effects of the complete interplanetary radiation field, not attenuated by the Earth's magnetic field.

Apollo Mission, Table 1 Summary of human flights in the Apollo program to the Moon

Apollo mission	Mission description	Launch date day/month/year	Stay lunar surface (h)	Astronauts
7	Earth orbit test	11/9/68	–	Schirra, Cunningham, Eisele
8	Circumlunar flight	21/12/68	–	Borman, Lovell, Anders
9	Earth orbit test of LM	3/3/69	–	McDivitt, Scott, Schweickert
10	Circumlunar flight, LM separation	18/5/69	–	Stafford, Cernan, Young
11	Lunar landing, sample return	16/7/69	22.2	Armstrong, Collins, Aldrin
12	Lunar landing, surface experiment package	14/11/69	31.5	Conrad, Gordon, Bean
13	Lunar landing aborted	11/4/70	–	Lovell, Swigert, Haise
14	Lunar landing, highland exploration	31/1/71	33.5	Shepard, Roosa, Mitchell
15	Lunar landing and rover, geological sampling	26/7/71	67	Scott, Worden, Irwin
16	Lunar landing and rover, geological sampling, Biostack and MEED experiments	16/4/72	71	Young, Mattingly, Duke

Apophis Asteroid

Gerhard Hahn

Asteroids and Comets, DLR, Institute of
Planetary Research, Berlin, Germany

Synonyms

(99942) Apophis

Definition

(99942) Apophis is an Aten-type asteroid, which will make a very close approach to our planet on April 13, 2029, passing within less than 40,000 km, close to the ring of geostationary satellites. Its size is about 375 m and its rotation period 30.6 h. This close approach will change the orbit substantially, from Aten type to Apollo.

History

Apophis was discovered on June 19, 2004 by R. A. Tucker, D. J. Tholen, and F. Bernardi at Kitt Peak. It was temporarily lost and rediscovered in December 2004. Shortly thereafter, the close approach in 2029 was realized; even a collision at that time was possible. This has been ruled out based on extensive observations, including radar; the orbital evolution after 2029 is still uncertain allowing an impact probability of 5.7×10^{-6} (see impact monitoring sites at JPL and the University of Pisa).

Apsidal Angle

Rory Barnes

Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In planetary dynamics, the apsidal angle is the angle between the directions of closest approach (the apse) of two planets, as measured from the origin of the coordinate system (usually the center of the star). This angle may change with time and is coupled to the eccentricities of the orbits. The apsidal angle may oscillate about a fixed value (called apsidal libration) or circulate.

Molecular evolution · In vitro evolution · RNA world · Combinatorial nucleic acid library · Ribozyme · Peptide

Definition

An aptamer (from the Latin *aptus*, fit, and Greek *meros*, unit or part) is an in vitro selected oligonucleotide or peptide molecule that binds to a specific target molecule. Nucleic acid aptamers are target-binding DNA or RNA molecules obtained by in vitro evolution. A peptide aptamer is an individual member of a library of random peptide sequences that can be selected for its ability to interact with a target molecule.

History

By the end of the 1980s, the possibility to chemically synthesize nucleic acid pools of random sequence, as well as the availability of all the required enzymes for nucleic acid amplification, allowed the selection of target-binding RNA molecules from combinatorial nucleic acid libraries. The term “aptamer” was coined to denote the in vitro evolved, target-binding RNA (Ellington and Szostak 1990), while the amplification-selection process was termed “systematic evolution of ligands by exponential enrichment” or SELEX (Tuerk and Gold 1990). The RNA aptamers selected in those two pioneering experiments were able to specifically bind different organic dyes and a viral enzyme – the bacteriophage T4 DNA polymerase – respectively. Three years later, the first RNA aptamer targeted to a small biomolecule was directed at ATP (Sassanfar and Szostak 1993).

Over the last two decades, a growing number of RNA and DNA aptamers have been developed against a variety of molecular targets, including simple ions; small molecules, such as amino acids, nucleotides, antibiotics, or metabolites; peptides; proteins; nucleic acids; macromolecular assemblies; viruses; organelles; or even whole cells (Klussmann 2006; Stoltenburg et al. 2007). In 2004, the first aptamer-based drug, called *Pegaptanib*, brand name *Macugen*, was approved by the US Food and Drug Administration in treatment for age-related macular degeneration (Gragoudas et al. 2004).

In parallel, peptide aptamers were obtained by high-throughput selection methods aimed at

identifying members of a randomized peptide library – usually attached at both ends to a given protein scaffold – by means of their interaction with a target molecule (Colas et al. 1996). Additionally, a method termed “mRNA display” allowed the in vitro selection of peptides and proteins with the desired target-binding properties (Roberts and Szostak 1997).

Overview

The preparation of a nucleic acid aptamer is currently easy and quick, since only 6–15 rounds of in vitro selection or evolution are typically required, using a combinatorial nucleic acid library as the starting material. Moreover, the sensitivity and specificity of the molecular recognition between a nucleic acid aptamer and its target rival those of the antibody-antigen pairs. Additionally, different ways to increase the resistance of aptamers to degradation by nuclease enzymes have been reported. These reasons, together with their cost-effectiveness, make nucleic acid aptamers not only relevant model systems to address the RNA world hypothesis (Joyce and Orgel 2006) but very useful tools in biotechnology with increasing applications in biosensing, diagnostics, and therapy (Klussmann 2006; Mayer 2009; Germer et al. 2013).

The outcome of an in vitro evolution process is usually monitored at the level of genotype, nucleotide sequence of the evolved aptamer, and phenotype, secondary/tertiary structure of the oligonucleotide, affinity and specificity of the aptamer for its target molecule. Although nucleic acid aptamers are artificial molecules, riboswitches have been considered “natural aptamers” embedded in messenger RNAs since they act as regulatory elements for gene expression by directly sensing small effector molecules (Zhang et al. 2010). Allosteric ribozymes that fuse one aptamer and one nucleic acid enzyme have been developed, the ribozyme activity being modulated by the binding of an effector molecule to the aptamer domain. The biotechnological applications of such “aptazymes” – also known as artificial riboswitches – are increasingly recognized (Wieland and Hartig 2008). Recently, the unveiled

ability of certain nucleic acid analogues to fold into three-dimensional structures allowed the in vitro evolution of aptamers harboring different molecular scaffolds, some of which bind their targets with an affinity similar to that of RNA or DNA aptamers (Pinheiro et al. 2012).

In addition to nucleic acid aptamers, the peptide aptamer approach has utilized small inert scaffold proteins to expose the randomizable peptide region. Alternatively, the mRNA display technique has been used to develop peptide aptamers, and “stand-alone” interfering peptides have also been selected. The ability of peptide aptamers to specifically interact with different proteins and other target molecules offers broad applicability in biochemistry and biomedicine (Mayer 2009; Li et al. 2011).

Aptamer-Based Biosensor

- [Aptasensor](#)

Aptasensor

Miguel Moreno

Centro de Astrobiología, CSIC, Madrid, Spain

Keywords

Aptamer · Biosensor · DNA · RNA

Synonyms

[Aptamer-based biosensor](#)

Definition

An aptasensor is a particular class of biosensor where the biological recognition element is a DNA or RNA aptamer. In an aptasensor, the aptamer recognizes the molecular target against which it was previously *in vitro* selected. The aptamer-target reaction is independent of both the type of detection system and the kind of transducer employed. Aptasensors can be easily multiplexed to detect a variety of aptamer-target reactions simultaneously.

History

Since the development of the first glucose biosensor in 1962 (Clark and Lions 1962), an extensive choice of biosensors has been developed. Among them, nucleic acid-based biosensors are of particular interest due to their practical applications in different fields of genomic research. In 1990 two independent groups simultaneously described aptamers as target-binding nucleic acid molecules (Tuerk and Gold 1990; Ellington and Szostak 1990). Adapting both technologies, aptamer-based biosensors were established in 1996 when Drolet and coworkers (Drolet et al. 1996) described a modification of the renowned enzyme-linked immunosorbent assay (ELISA) which utilized an aptamer instead an antibody as biorecognition element. The assay was named “enzyme-linked oligonucleotide assay” (ELONA), and this evidence opened the door to novel ways of biosensing using nucleic acids to detect a wide range of molecules in a variety of formats.

Overview

Aptamers are attracting interest in the areas of therapeutics and diagnostics and offer themselves as ideal candidates for use as the recognition elements in biosensors since they possess many advantages over the state-of-the-art affinity sensors. Aptasensors show very high sensitivity, specificity, and reproducibility against a wide

variety of targets. Thus, they are rapidly emerging as promising candidates for high-throughput analytical methods that have to deal with tiny quantities of the queried analytes. Analogous to immunoassays (those based on the antigen-antibody interaction), aptamer-based bioassays can adopt different configurations to transduce biorecognition events, including aptamer-based microarrays (Collett et al. 2005), aptamer-capped gold nanoparticles (Song et al. 2012), quantum-dot aptamer conjugates (Levy et al. 2005), and electrical (Willner and Zayats 2007) and electrochemical (Moreno et al. 2011) aptasensors, among many others (Citartan et al. 2012).

Aptamers offer an extensive range of advantages over other existing biological recognition elements in terms of stability, design flexibility, and cost-effectiveness. To name a few, aptamers can bind to their targets with affinities and specificities equivalent to those of monoclonal antibodies and can be selected to bind a wide range of targets including those that are toxic or not inherently immunogenic. Additionally, the affinities and specificities of aptamers can be easily tailored (in contrast to those of antibodies) and can be more readily engineered than antibodies for their use as biosensing elements. Finally, aptamers can be synthesized, chemically modified, and stored until needed and are resistant to denaturation and degradation. The in-depth knowledge of aptamer conformational properties and ligand-binding mechanisms has triggered profound attention among researchers for developing aptasensor bioassays, as reflected in the exponential increase of published articles (Citartan et al. 2012).

Nevertheless, aptasensors compete with other well-established biosensors, essentially antibodies-based ones, and they have been mainly focused on the applications where antibodies cannot achieve the desired goals. The most straightforward application of aptasensors lies in the fields of food safety testing and environmental pollution control. Thus, aptasensors developed for the detection of small molecule contaminants including antibiotics, toxins, pesticides, and heavy metals (that may be present in a wide variety of food products and environmental samples)

are of particular interest (Cho et al. 2009; Fischer et al. 2007).

In astrobiology, aptasensors are called to be a functional tool for the detection of both molecules with limited antigenicity present in different extreme environments and biosignatures of extinct or extant life in planetary exploration. In the field of biomarker detection in space missions, robust and very stable aptasensors might be developed with extended capabilities to overcome the extreme conditions of long travel time and planetary exploration.

Aqueous Alteration

Yoko Kebukawa¹ and Michael E. Zolensky²

¹Faculty of Engineering, Yokohama National University, Yokohama, Japan

²ARES, NASA Johnson Space Center, Houston, TX, USA

Keywords

Meteorites · Asteroids · Water · Minerals · Organic matter

Definition

A secondary process whereby liquid water modified the nature of anhydrous primary nebular components. In general, this process induced decomposition and changed the structures and compositions of primary minerals and formed secondary minerals in their place. This process occurred in the early history of meteorite parent bodies that contained water ice. The most effective heat source is considered to be the decay of short-lived radioactive nuclide such as aluminum 26, but other causes have been suggested. The degree of aqueous alteration of meteorites is categorized as type 1 (most altered) to type 3 (least altered), according to mineralogy and petrology.

Overview

Some meteorites provide evidence that liquid water was widespread and very active during the early history of some meteorite parent bodies—asteroids and comets. Characteristic secondary minerals are hydrous minerals such as

serpentines, smectites, micas, and tochilinite, as well as sulfides, oxides, phosphates, and carbonates (e.g., Brearley 2006). Hydrous phases are observed spectroscopically on C-complex asteroids (C-, G-, F-, and B-type asteroids) that are plausibly to the source of some carbonaceous chondrites (e.g., Vilas and Gaffey 1989). The degree of aqueous alteration is classified into petrologic types 1–3, based on the abundances of chondrule glass and metal, sulfide compositions, matrix mineralogy and quantity, carbon and water content, and stable isotopic compositions (Van Schmus and Wood 1967). Type 1 is most aqueously altered and type 3 is least altered. CI, CM, and CR carbonaceous chondrites are extensively aqueously altered. CI group contains type 1, the CM group contains type 1 and 2, and the CR group contains type 1–3. CM chondrites have been further assigned to subtype, least altered CM2.6 to most altered CM2.0 (=CM1) (Rubin et al. 2007). There are no type 1 and 2 meteorites in other groups of carbonaceous chondrites (e.g., CV and CO) and ordinary chondrites; however, some samples of all of these latter groups show some degree of aqueous alteration (e.g., Grossman et al. 2000). In many cases, the effects of aqueous alteration have been obscured by subsequent thermal metamorphism (Tonui et al. 2014).

The most widely accepted location of aqueous alteration is meteorite parent bodies. There are also possibilities for limited alteration with water ice or vapor in the nebula (e.g., Ciesla et al. 2003). After accretion of planetesimals, water ice melted due to either heating by decay of short-lived radioactive nuclides, impacts, or solar heating, triggering aqueous alteration. Isotopic chronologies based on Mn-Cr isotope measurements of carbonates revealed that aqueous alteration occurred as long as $4563.4 \pm 0.4/-0.5$ Myr ago (~ 4.8 Myr after calcium-aluminum-rich inclusion (CAI) formation) for CM chondrites (Fujiya et al. 2012). However, these dates are now being reassessed.

Aqueous alteration models have been constructed based on mineralogic assemblages, stable isotopes, and thermal evolution (e.g., Clayton and Mayeda 1999; Grimm and Mccsween 1989; Zolensky et al. 1989). Depending on the

heating mechanism, thermal evolution largely depends on the canonical values of ^{26}Al , porosity, water/rock ratio and size of body, and orbital histories. Conditions of aqueous alteration varied for the different meteorite groups. Temperatures have been estimated approximately as 20–150 °C for CI, 0–80 °C for CM2, and 50–150 °C for CR (Brearley 2006 and references therein). Estimation of water/rock ratios are 1.1–1.2 with $\text{pH} = 7\text{--}10$ and $f\text{O}_2 > 10^{-55}\text{--}10^{-70}$ for CI, and water/rock ratios are 0.3–0.6 with $\text{pH} = 7\text{--}12$ and $f\text{O}_2 < 10^{-85}$ for CM2 (Zolensky et al. 1993; Zolensky et al. 1989). Again, these estimates depend on model assumptions.

During the aqueous alteration, formation and evolution of organic matter would be expected. For example, during early stages of aqueous alteration, macromolecular organic matter and amino acids can be produced from simple molecules such as formaldehyde and ammonia (e.g., Cody et al. 2011; Kebukawa et al. 2017). Further alteration modifies the compositions of organic matter, e.g., decreases H, N, O contents and aliphatics and oxygen-bearing functional groups (e.g., Alexander et al. 2007, 2014). Among amino acids, ω -amino acids dominate in heavily altered chondrites in contrast to α -amino acids which dominate in the less-altered ones, probably due to lower stabilities of α -amino acids and/or formation of ω -amino acids by Fischer-Tropsch-type (FTT) reaction (e.g., Elsila et al. 2016). Larger L-isovaline enrichments in the aqueously altered compared to less-altered meteorites suggest that aqueous alteration promoted L-isovaline excesses on meteorite parent bodies (Glavin and Dworkin 2009).

Aqueous alteration provided abundant water in the form of hydrated minerals (e.g., Alexander et al. 2012), as well as a diverse suite of organic compounds formed in parent bodies in addition to pre-accretional organic matter (e.g., Schmitt-Kopplin et al. 2010) to the early Earth.

Definition

An aqueous interface is the dividing surface between two media, one of which is water.

History

Atmospheric interfaces including rocks and clays have long been considered in the origin of life scenarios. Aqueous interfaces (water surfaces) as found on oceans, lakes, rivers, and atmospheric aerosols were first suggested by Goldacre (1958) to be interesting in a prebiotic context due to their ability to concentrate organic molecules and subsequently fold and pinch off into enclosures reminiscent of cells. The use of Global atmospheric aerosols were pointed out in this context (Shah 1972) and suggested as effective prebiotic micro-reactors in different contexts later (Lerman 2010; Dobson et al. 2000; Tverdislov and Yakovenko 2008). In addition, aqueous interfaces have recently been suggested as favorable environments for biomolecular synthesis that is difficult or impossible in the bulk ocean (Dobson et al. 2000; Ruiz-Bermejo et al. 2010; Griffith et al. 2012).

Overview

Aqueous interfaces are found throughout nature: at the surface of lakes and oceans, at the surface of atmospheric aerosol particles, or even at the interface between a membrane and its surrounding

bulk water environment. Air-aqueous interfaces are particularly interesting in an astrobiological context due to their provision of a unique reaction environment, having the ability to concentrate and align surface active molecules (Goldacre 1958; Shah 1972). It was pointed out that the vast collective surface area of atmospheric aerosols provides diverse and fluctuating environments for chemistry and is applicable to any rotating planetary body with a liquid ocean (Dobson et al. 2000; Griffith et al. 2012). A planet rotating on a tilted axis results in thermal and pressure gradients that produce wind. This wind acting on a liquid ocean produces sea spray from which aqueous atmospheric aerosols are born (as depicted in the Fig. 1). Any organic material residing at or near the ocean surface will be entrained in these aerosols and can partition to their surface (an aqueous interface), forming a surfactant film around an aqueous core.

These interfaces allow for concentration of reactant species over the bulk aqueous solution, alteration of the ionization state of surface-residing reactants, and orientation of amphiphilic molecules, and they can even promote chemistry that is inaccessible in bulk water (Griffith and Vaida 2013). One example of a key reaction made possible by an aqueous interface is the formation of peptide bonds in the absence of

Aqueous Interfaces,

Fig. 1 Depiction of birth of aerosols from sea spray as well as schematic representation of peptide bond formation at the air-aqueous interface from amino acid (AA) precursors

enzymatic catalysis (Griffith and Vaida 2012) illustrated schematically in Fig. 1. Peptide bonds are a key bond in modern biology as they are the link between amino acid building blocks in proteins (one of the three principle biopolymers along with RNA and DNA). In addition, theoretical and experimental studies have been devised to investigate the interaction and folding of bimolecular assemblies at the surface of liquid water to model systems of biophysical interest (Pratt and Pohorille 2002).

Aqueous Minerals

- [Mars, Hydrated Minerals](#)

Aquifer (Mars)

Alessandro Airo
Institut für Geologische Wissenschaften Tektonik und Sedimentäre Geologie, Freie Universität Berlin, Fachbereich Geowissenschaften, Berlin, Germany

Definition

It is widely accepted that liquid water was present on the surface of Mars during its early history. Although parts of this water have vanished into space or were consumed in chemical reactions, substantial amounts are still present today. The current physical conditions on Mars' surface usually do not allow liquid water to be stable, and therefore, it occurs as water ice within the pore space of the permafrost soil or as few km-thick polar ice caps. It can be assumed that at a certain depth below the surface, usually estimated to be a few kilometers, the cryosphere transitions into an aquifer (Lasue et al. 2013). The depth at which the water ice turns into groundwater depends on not well known factors, such as the water salinity, the soil porosity and permeability, or the geothermal gradient and thermal conductivity of the subsurface. The presence of groundwater on Mars is

insofar of interest to astrobiologists as aquifers on Earth are populated by microbial life down to a depth of a few kilometers (Michalski et al. 2013).

Arachnoid

Jörn Helbert
DLR, Institut für Planetenforschung, Berlin,
Germany

Definition

An Arachnoid is a type of landform only seen on the surface of ► [Venus](#), which is believed to have a volcanic origin. Arachnoids get their name from their resemblance to spider webs. They appear as concentric ovals surrounded by a complex network of fractures, and are spanned up to 200 km. Over 30 arachnoids have been identified on Venus, so far.

Definition

The *Archaea* are a phylogenetically coherent group of prokaryotes that have a different organization than the *Bacteria*.

History

Woese and Fox (1977) proposed that prokaryotes were not a monophyletic group. Based on the comparison of their small subunit ribosomal RNA sequences, the prokaryotes comprise two distinct evolutionary lineages that are represented by the *Bacteria* and the *Archaea* (that formerly were designated as Archaeobacteria by Woese et al. 1978). The concept of a third domain of life, which explained several structural, metabolic, and molecular differences with respect to other prokaryotes, was initially poorly accepted by the scientific community. However, the concept of the *Archaea* was advanced through studies and meetings carried out by O. Kandler, W. Zillig, and K.O. Stetter, among others. The *Archaea* have similarities and are considered phylogenetically more closely related to the *Eukarya* (Woese et al. 1990).

Overview

Archaea have distinct molecular characteristics that clearly distinguish them from the *Bacteria* and the *Eukarya*, and evolutionary studies have highlighted their role in the development of life on our planet. *Archaea* have been associated with extreme environments and many of them are extremophilic microorganisms, showing interesting characteristics and applications for industrial and other purposes. Many of them are considered to be microorganisms that are able to grow on the limits of life. Their ability to thrive in extreme environments has expanded the horizons for Astrobiology as they are considered counterparts for extraterrestrial life.

The *Archaea* are characterized by a cellular morphology similar to those of most *Bacteria* (rods, cocci, irregular cells, etc.). However, myceliar or multicellular stages with cellular differentiation have not been described. On the contrary, unique morphologies have been described for some *Archaea*, such as the square flat cells of some haloarchaea (*Haloquadratum walsbyi*) or amoeba-like cells (*Thermoplasma* and other microorganisms). Other characteristics of the *Archaea* that define their differential status with respect to the other living organisms are: (1) the presence of phytanyl ether instead of fatty acid ester lipids in their membranes; (2) the absence of peptidoglycan (murein) in their cell walls and a frequent presence of proteinaceous S-layers (only a few have a polysaccharide cell wall), as well as the absence of a periplasmic space; (3) their complex DNA-dependent RNA polymerases (early in vitro studies using several inhibitors showed that the transcription machinery in *Archaea* is more closely related to that of *Eukarya* than to *Bacteria*); the sequences of the archaeal RNA polymerases resemble some eukaryotic RNA polymerases and consist of up to 13 different units; and (4) although the translation machinery of *Archaea* is similar to that of bacteria (70S ribosomes with 50S and 30S subunits, similar length ribosomal RNAs, transcriptional and translational coupling, etc.), there are an important number of specific features not present in

Bacteria, some of which are specific to *Archaea*, while others are similar to *Eukarya*. For example, almost all antibiotics that inhibit bacterial translation are ineffective in the *Archaea*; *Bacteria* use *N*-formyl-methionyl-tRNA for translational start codons, while *Archaea* use unmodified initiator methionine in translation, similar to *Eukarya*. Besides, *Archaea* and *Eukarya* share a common characteristic, elongation factor 2 (EF-2), which is ADP-ribosylated by diphtherial toxin.

The *Archaea* are subdivided into five phyla, of which two, the *Crenarchaeota* and the *Euryarchaeota*, are most extensively studied. The classification of *Archaea* has been widely discussed and several proposals have been published. The most widely accepted include the *Archaea* as a higher taxon with the range of *Domain*, which includes the following five phyla: *Crenarchaeota*, *Euryarchaeota*, *Nanoarchaeota*, *Nanohaloarchaeota*, and *Thaumarchaeota* (Parte et al. 2020). The phylum *Crenarchaeota* includes a single class, *Thermoprotei*, with five orders: *Acidilobales*, *Desulfurococcales*, *Fervidococcales*, *Sulfolobales*, and *Thermoproteales*. The phylum *Euryarchaeota* includes nine classes: *Archaeoglobi*, *Halobacteria*, *Methanobacteria*, *Methanococci*, *Methanomicrobia*, *Methanonatronarchaeia*, *Methanopyri*, *Thermococci*, and *Thermoplasmata*. The phylum *Nanoarchaeota* includes a sole genus, *Nanoarchaeum*. Finally, the phylum *Thaumarchaeota* includes the class *Nitrososphaeria*, with two orders: *Nitrosopumilales* and *Nitrososphaerales*. Other phyla including noncultivated *Archaea* have been recently described: *Candidatus* Aigarchaeota, *Candidatus* Diapherotrites, *Candidatus* Hadarchaeota, *Candidatus* Huberarchaeota, *Candidatus* Hydrothermarchaeota, *Candidatus* Korarchaeota, *Candidatus* Lokiarchaeota, *Candidatus* Parvarchaeota, *Candidatus* Thermoplasmata, *Candidatus* Undinarchaeota, and *Candidatus* Verstraetearchaeota.

The phylum *Euryarchaeota* includes two of the most typical groups that were identified in the early studies by Woese and coworkers as members of the *Archaea*: the methanogens and the haloarchaea (also designated as halobacteria).

The methanogenic *Archaea* are anaerobic organisms that produce methane as the major end product of their metabolism. Phylogenetically, methanogens are very diverse and are represented by a large number of species belonging to many genera, grouped into 16 families within eight orders. They are found in a variety of anoxic environments such as ocean and lake sediments, hydrothermal vents, animal digestive tracts, and anaerobic sludge digesters. The typical growth compounds of methanogens are H_2 and CO_2 , or short-chain (C_1 - C_5) organic compounds (formate, acetate, ethanol, trimethylamine, etc.). H_2 is used as electron donor for CO_2 reduction, and electrons can also be derived from formate, CO, or specific alcohols. Among the microorganisms that have been used as models for studying methanogenesis are species of the genera *Methanobacterium*, *Methanothermobacter*, *Methanobrevibacter*, *Methanosarcina*, and *Methanococcus*, among others (Rosenberg 2014; Madigan et al. 2020).

Haloarchaea are represented by a group of extremely halophilic aerobic or anaerobic *Archaea* (Sorokin et al. 2016), which taxonomically are placed within a single class, *Halobacteria* (Oren et al. 2017), which comprises three orders and six families. Currently they are represented by over 70 genera and a large number of species that are characterized by their Na^+ requirements. They are considered to be organisms that are able to grow under higher salt concentrations, in saturated NaCl habitats. Their optimal NaCl requirements are in the range 3.5–4.5 M NaCl and they are not able to grow in media without NaCl. Thus, they have a specific requirement for NaCl, which has led to detailed studies of their mechanisms of haloadaptation. In contrast to most other prokaryotes, which accumulate intracellular organic compounds designated as compatible solutes, haloarchaea compensate for the high salt concentration in the environment by accumulating ions, mainly up to 5 M KCl. They are normal inhabitants of hypersaline environments, being the predominant microbiota of saturated ponds of salterns and salt lakes (they may reach high cell densities, $>10^7$ cell ml^{-1}); they are also found in salt or salted

products (salted fish or meats, salted fermented foods), salt deposits (mines), salted hides, and saline soils. Most haloarchaea grow at neutral pH values but some species are haloalkaliphilic, being able to grow optimally at alkaline pH and inhabiting soda lakes. Other typical features of haloarchaea are: their production of red- to pink-pigmented colonies due to the presence of bacterioruberins (C_{50} carotenoids), although there are a few exceptions; the presence, in some of them, of retinal-based pigments (bacteriorhodopsin) that act as a proton pump driven by light energy; or the presence of typical archaeal polar lipids, with ether-linked phosphoglycerides that can be easily detected by thin-layer chromatography (a feature that is widely used for the taxonomic differentiation of most genera of haloarchaea) (Oren et al. 2017). Haloarchaea are excellent models for the study of the molecular biology and other structural features of *Archaea*, as well as their mechanisms of adaptation to extreme conditions of salinity, alkaline pH, and moderate temperature, and several species have been used for such purposes due to their ease of manipulation under laboratory conditions: they grow in complex media (with the appropriate salt content) under aerobic conditions using the standard procedures utilized for most non-fastidious prokaryotes. Some species used for such studies include *Halobacterium salinarum*, *Haloarcula marismortui*, *Haloferax volcanii*, and, more recently, the square haloarchaeon *Haloquadratum walsbyi* (isolated and referred to as “Walsby’s square bacterium”). In addition, several biotechnological applications have been suggested, such as the commercial production of bacteriorhodopsin, the production of extracellular hydrolytic enzymes or exopolysaccharides, the use of polyhydroxyalkanoates (PHAs) as bioplastics, or the production of halocins (archaeocins, proteinaceous archaeal antimicrobials).

With a few bacterial exceptions, most hyperthermophiles (defined as organisms showing optimal growth at 80 °C or higher) are species of *Archaea*. They are inhabitants of hot springs, solfataric and volcanic areas, deep-subsurface aquifers, submarine vents (“black smokers”),

etc. Hyperthermophiles include several methanogens, as well as members of a variety of genera of the *Archaeoglobales*, *Thermococcales*, *Acidilobales*, *Desulfurococcales*, *Sulfolabales*, and *Thermoproteales*. They are excellent models for the study of the metabolisms of sulfur and inorganic sulfur compounds; many species use inorganic sulfur compounds as electron acceptors or donors. Some of the most hyperthermophilic organisms known are *Pyrolobus fumarii* (optimal growth at 106 °C, range 90–113 °C), *Pyrodicticum occultum* (optimal growth at 105 °C, range 85–110 °C), *Pyrococcus furiosus* and *Pyrococcus woesei* (optimal growth at 100–103 °C, range 70–105 °C), *Pyrobaculum aerophilum* (optimal growth at 100 °C, range 75–104 °C), and *Pyrobaculum islandicum* (optimal growth at 100 °C, range 74–102 °C).

The phylum *Nanoarchaeota* is known for a single species, *Nanoarchaeum equitans*, to date a hyperthermophilic archaeon that lives in a symbiotic association with the Crenarchaeote *Ignicoccus*, a sulfur-dependent anaerobic hyperthermophile. The cells are spherical and only about 400 nm in diameter; they grow attached to the surface of a specific archaeal host (Hubber et al. 2002). This archaeon was isolated from a submarine hot vent, but recent studies have shown that nanoarchaea may be widely dispersed in hyperthermophilic and mesophilic halophilic environments (Casanueva et al. 2008; Rinke et al. 2013). Cultivated *Archaea* belonging to the phylum *Nanoarchaeota* are also known to associate with other haloarchaea, thereby compensating for their own auxotrophies. These diminutive but ubiquitous microorganisms thrive in hypersaline habitats that they share with haloarchaea (Hamm et al. 2019; La Cono et al. 2020).

Basic Methodology

The study of the *Archaea* can be accomplished using the classical culture-dependent methods and the more recently developed culture-independent sequencing techniques which have provided access to unknown genomic data from until now inaccessible archaeal lineages.

Key Research Findings

The *Archaea* play a key position in the Tree of Life and constitute an important fraction of the microbial diversity with a wide metabolic potential.

Future Directions

Discovery of novel major archaeal taxa is still challenging. The origin of this domain and its relationships with *Bacteria* and *Eukarya*, as well as its role in the environmental ecology and in human health and disease, is not yet clear.

Archaeon biosignatures

Definition

The Archaeon is the period of geological time between 3.8 and 2.5 billion years ago when life is thought to have emerged on Earth. Traces of Archaeon life are preserved in rare, fragmentary, and often highly altered rock sequences. Morphological evidence for Archaeon life is provided by

microfossils, stromatolites, and microbially induced sedimentary structures. Chemical evidence for life is recorded by stable isotope ratios of carbon and sulfur in particular. These various biosignatures provide insights into the nature of early Archaean ecosystems and much remains to be learned about the predominant microbial metabolisms at this time and their distribution. Recognizing and distinguishing abiotic mimics from bona fide microbial also remains an important challenge. The effort to refine our understanding of microbial biosignatures in the Archaean rock record is essential to designing strategies for seeking life elsewhere in our universe and for ratifying this evidence.

Overview

This review first explains *where* to look for Archaean traces of life, *what* evidence Astrobiologists seek, and *how* these rocks are investigated. Then, a review of current research findings is given focusing on selected case studies of microfossils, stromatolites, and endolithic microborings.

Basic Methodology

Locating Well-Preserved Archaean Rocks from Habitable Environments

The search for Archaean traces of life relies upon geological mapping and radiometric dating to locate rocks of the Archaean age. Worldwide, there are two cratons that preserve intact sequences of the Early Archaean age where now metamorphosed volcanic and sedimentary rocks are preserved in greenstone belts – so-called because of the green color conferred by their typical metamorphic minerals. The first of these is the Pilbara of Western Australia and the second is the Kapvaal Craton of South Africa and Swaziland, a region known as the Barberton Mountainland. In recent years, there have been several scientific drilling projects that have targeted these Archaean sequences to seek the earliest evidence for life. Scientific drilling yields continuous sequences of rock unaffected by alteration at the

earth's surface allowing more complete investigation of well-preserved biosignatures within their geological context. Older Archaean rocks of between 3.8 and 3.7 Ga from Greenland and Labrador are of much higher metamorphic grade and more intensely deformed. Thus, any potential traces of life in these rocks have been heavily modified and/or completely destroyed.

The search for Archaean morphological traces of life has traditionally centered on meta-sedimentary rocks, in particular cherts and carbonates (Javaux 2019). Geological environments where microbial remains are most likely to be preserved are those where rapid, contemporaneous mineralization entombs and permineralizes living organisms. Precipitation of microcrystalline silica is a good example and can preserve cellular remains with exceptionally high fidelity. Cherts are formed in the vicinity of hydrothermal vents and hot springs, and as chemical sediments on the Archaean seafloor. Likewise, chemical traces of life are normally sorted in meta-sedimentary rocks formed at or near the Earth's surface. Metasediments that have experienced greater than greenschist facies-grade metamorphism have proven controversial when interpreting putative biosignatures.

An important criterion for establishing the biogenicity of a candidate, Archaean traces of life is the demonstration that the geological environment was viable for life. This translates to the assessment of habitability or, in other words, mapping out the environmental limits to life. There are a number of first-order differences between the Archaean world and the recent earth that should be borne in mind. Firstly, Archaean surface environments were largely anoxic, the atmosphere was probably rich in carbon dioxide and methane and there was no ozone layer. Secondly, seawater was supersaturated with silica, its pH, temperature, and salinity are widely debated and certainly differed from today, with the ocean likely being warmer. Thirdly, exactly when Archaean plate tectonics began and the nature of early tectonic processes is unclear with profound implications for the cycling of nutrients on the earth and the oxidation of key geological reservoirs.

Demonstrating Syngenetic and Endogenicity

All candidate traces of life must be shown to be truly ancient and **syngenetic**, that is, contemporaneous to the host rock. It is not possible to date organic remains and fossils directly, but it is often possible to use radiometric techniques to date the host rocks. These methods are described elsewhere in this encyclopedia, and the radiometric system chosen will depend on the minerals available, the fluid and metamorphic history of the rock, also the anticipated age and precision required.

Microbial remains and carbonaceous matter found within rocks can be **endogenetic** and formed at the same time as the host rock, or they can be derived from external fluids that entered the rock at a later stage via circulating fluids, or younger microbes that entered through fractures/pore space. The latter type of material is unreliable biosignatures. Careful thin-section observations are required to establish the context of the candidate biosignature and to establish that they are hosted by primary mineral phases and are therefore endogenetic, and hopefully cross-cut by any later-stage mineral veins or fractures. Early biological remains may also show evidence of compaction, for example, large spherical organic microfossils can be flattened to ellipses during compaction, although if the rocks have experienced early silicification, this criterion will not hold. Raman spectroscopy can also be useful in this regard, to compare the metamorphic history of organic remains to material in the surrounding rock. For, carbonaceous remains to be syngenetic their thermal maturity as measured by Raman geothermometry should match that of the host rock.

Textural Evidence of Life: Testing Abiotic Scenarios

Morphological complexity is often regarded as a diagnostic criterion for life. But it must be remembered that complex shapes do not require complex causes and can arise naturally in physio-chemical systems, as shown, for example, by snowflake growth. The interpretation of candidate morphological evidence for life, therefore, proceeds together with exploration and refutation of potential abiotic mimics, reviewed briefly here.

With reference to stromatolites, it has been recognized for some years that abiotic processes can generate laminated abiotic deposits, for example, in numerical simulations (Grotzinger and Rothman 1996) and laboratory experiments (McLoughlin et al. 2008), and that these can produce complex morphologies such as branching. Chemical precipitation can also form laminated deposits, but an understanding of the geological environment can identify localities where this may be most likely, for example, in supersaturated water columns, or terrestrial sinter deposits. Also, the laminar geometries, in particular isopachous laminae, that is, of constant thickness, and with radiating crystal fabrics at the microscale can be used to identify production by chemical precipitation. Conversely, evidence of the trapping and binding of detrital sediment on steep-sided microbialites would support biological involvement. Further exploration of the biological versus abiological contribution to stromatolite growth can be found elsewhere in this volume. In Archaean rocks, where the primary microfabrics have been overprinted and organic remains destroyed, caution must be exercised before inferring a biological origin.

Concerning microfossil remains, the challenge of demonstrating biogenicity is particularly acute for simple-spheroidal bodies found in Archaean cherts. Here, processes such as the recrystallization of silica gel leading to the displacement of organic matter can generate spheroidal shapes, even conceivably filamentous and segmented morphologies (Brasier et al. 2005). Here, the examination of the carbonaceous ultrastructure to demonstrate whether the candidate microfossil is hollow and shows evidence of a cell wall or sheath can be helpful. Also looking at the size distribution of the population to test if this resembles a biogenic population, or a large abiotic community (Brasier et al. 2006). Crystal-garden-type experiments that precipitate microfossil-like biomorphs from metal salts mixed with sodium silicate gels (García-Ruiz et al. 2003 and Fig. 1b) have emphasized the diversity and complexity of microtextures that can be generated abiotically. Even more worrying, is the discovery that organic compounds produced by the abiogenic

breakdown of iron-carbonate can condense onto these biomorphs during mild heating, thereby mimicking both the morphological and chemical signatures of ~3.5 Ga “microfossils” (García Ruiz et al. 2003).

Concerning candidate endolithic microborings, several abiotic microtunnelling processes have been postulated (McLoughlin et al. 2010). The first are so-called “ambient inclusions trails” formed by the migration of a mineral grain, usually pyrite through a mineral matrix, most commonly chert, leaving a hollow cavity behind that can sometimes be lined by organics. If the terminal inclusion is a corrosive bitumen droplet rather than pyrite, the microtunnel cross-section may be less angular and therefore more difficult to identify as abiotic (McLoughlin et al. 2010 and refs therein). A second group of processes that may mimic candidate microborings especially in meta-volcanic glass, is the growth of metamorphic minerals during low-grade seafloor or regional metamorphism to form chains or strings of crystals with morphologies and distributions that resemble mineralized microtunnels. Possible examples will be discussed and reviewed below.

Lastly, it should be appreciated that organic matter or kerogen with carbon and nitrogen isotope ratios that are similar to life can be found in a wide range of environments, including the interstellar medium, meteorites and comets, and also a range of geological environments. Most relevant to discussions concerning candidate Archaean traces of life are seafloor-hydrothermal processes, spanning high to relatively low-temperature conditions that can generate negatively fractionated C isotope values (Sforna et al. 2018 and refs therein). When attempting to identify unambiguous biogenic traces of life, it is important that all available lines of evidence are combined, integrating morphological, chemical, and geological evidence across the outcrop (meters), thin section (mm- μ m), and ultrastructural (nm) scale to try distinguishing biotic from abiotic remains.

Chemical Evidence of Life: Elemental and Isotopic Signatures

Isotopic ratios preserved in ancient rocks may record past biological activity and can be

measured by mass spectrometry to test for the presence of life and often constrain the microbial metabolisms involved. Here, the focus is on carbon and sulfur isotopes, which are the main isotopic tools used in the search for Archaean life. A key distinction is made between bulk stable isotope studies, which give information about global systems and reservoirs, versus in-situ studies that can be texturally connected to specific morphological biosignatures and are therefore very powerful tools in evaluating biogenicity.

Carbon Isotopes

The ratio of ^{12}C to ^{13}C preserved in organic matter and associated carbonates provides constraints on ancient microbial processes. Different microbial metabolisms and various abiotic processes impart differing ranges in C isotope fractionation that are described in detail elsewhere in this volume. If ancient organic matter can be shown to be syngenetic and endogenetic to the host rock, then its carbon isotopic values can be used to constrain the ancient microbial metabolisms. Typical Archaean organic matter is found to have a $\delta^{13}\text{C}$ value of -20‰ relative to inorganic carbonate leading many researchers to claim that biological activity began 3.8 billion years ago (Schidlowski 2001). A range in C isotope values is found in Archaean organic matter, especially from high-magnification in-situ studies and so a variety of microbial metabolisms have been proposed, including anoxygenic photosynthesis from C isotopes in the range of -20‰ to -30‰ measured on kerogen, for example, (Tice and Lowe 2004); and methanogenesis from very low C ratios of -56‰ measured on methane-bearing fluid inclusions (Ueno et al. 2006). These $\delta^{13}\text{C}$ values are certainly consistent with life but, unfortunately, carbon isotope fractionation patterns when taken alone are not a uniquely biological signal. This is because there are alternative non-biological explanations for such light carbon isotopic values that need to be excluded and these can be the source of much debate in Archaean rocks. For example, Fischer–Tropsch type (FTT) reactions between CO and metals, or the

metamorphic reduction of siderite can generate carbon isotope fractionations that lie within the “biological domain.” Thus in the early rock record, carbon isotope values need to be integrated with other isotope systems along with an understanding of the geological context to be accurately interpreted.

Sulfur Isotopes

Microorganisms that metabolize sulfur compounds are one of the most deeply rooted groups in the Tree of Life. Sulfur isotopes preserved in ancient sulfides, especially pyrite, along with sulfate minerals like barite, are used to trace ancient microbial metabolisms. The sulfur cycle on the early Earth was markedly different from the later Precambrian, because in the absence of atmospheric oxygen the photolysis of volcanic S_2 could produce elemental S and sulfate aerosols. Sulfate ions can be used by microbial sulfate reducers and may also be used to oxidize organic compounds by anaerobic respiration, whilst elemental S could be metabolized via microbial disproportionation. (For further explanation of microbial sulfur cycling see elsewhere in this volume.) Both microbial sulfate reduction and abiotic photolysis reactions can impart large fractionations in ^{34}S relative to ^{32}S and by investigating the isotope fractionation patterns recorded by the four stable isotopes of sulfur (^{32}S , ^{33}S , ^{34}S , ^{36}S) it is possible to distinguish microbial signatures from abiotic processes in the atmosphere and hydrothermal-volcanogenic systems.

The S isotope record from ~2 Ga onwards shows $\delta^{34}S$ fractionations of 50–60‰ between sulfides that are depleted relative to co-existing sulfates and this has been attributed to microbial sulfate reduction. In older rocks, such fractionations are much smaller with most sedimentary sulfides older than ~2.7 Ga showing a narrow $\delta^{34}S$ range. Evidence of microbial sulfate reduction is found in rocks between 3.5 and 2.7 Ga, particularly from in-situ studies of microscopic sulphides but not in bulk samples (Shen and Buick 2004). This has been taken to suggest that microbial sulfate reduction was present locally, but not widespread because of low-sulfate concentrations in the Archaean oceans.

Key Research Findings

Microfossils

Microfossils are the remains of carbonaceous microbial cells and display a range of shapes that include: coccoids (simple spheres), filaments that may be septate and/or branched, and lenticular/ellipsoidal bodies. Microfossils found in Archaean rocks have experienced diagenetic alteration often followed by multiple metasomatic and metamorphic events, and commonly extended weathering histories. Combined with the fact that these microorganisms are amongst the most primitive with simple morphologies, their identification as *bonafide* traces of life can be challenging, with many instances of candidate Archaean microfossils being subsequently reidentified as abiotic mimics. Several workers have therefore developed and advanced criteria to establish the biogenicity of ancient microfossils (Brasier et al. 2005 and refs therein) and examples of how these are applied will be reviewed below.

An instructive example of how the biogenicity of candidate Archaean microfossils is assessed comes from the ~3.45 Ga Apex Chert of Western Australia that is now famous for engendering a vigorous debate regarding the oldest microfossil-like objects (Fig. 1c). In the 20 years since their discovery, these “microfossils” have become the cornerstone of textbook descriptions of an early Archaean biosphere. This changed, however, when a re-examination of the “microfossils” called into question their biogenicity (Brasier et al. 2002). These authors argued that the geological context, morphology, and distribution of the “microfossils” are more consistent with an origin as abiotic graphite artifacts, produced by the recrystallization of amorphous silica to spherulitic chert. The principal lines of evidence from (Brasier et al. 2002) are summarized in Table 1 and contrasted with the original interpretation of (Schopf and Packer 1987), an origin for these “microfossils” as oxygen-producing cyanobacteria-like organisms now seems highly unlikely. There have been several subsequent studies that have investigated the morphology of the Apex microfossil-like structures and compared them to younger less-metamorphosed samples, also studies that have

Archaean Traces of Life, Table 1 Contrasting lines of evidence and their interpretation collected from the ~3.45 Ga Apex Chert of Western Australia and containing “microfossil” structures

Lines of evidence	Brasier et al.	Schopf et al.
Environment of deposition	Deep marine seafloor cherts with intrusive hydrothermal dyke cherts	Shallow marine silicified sediments
“microfossil” morphology	Sheets and wisps of carbonaceous material concentrated around the rims of silica spherulites and rhombic crystal inclusions	Eleven taxa of filamentous “microfossils”
Laser Raman analysis	The carbonaceous material has a graphitic Raman signature, and the “microfossil” signature is indistinguishable from the matrix carbonaceous material	The “microfossils” have a Raman signature that is argued to be comparable to disordered kerogenous carbon from younger biogenic assemblages
Carbon isotopes	$\delta^{13}\text{C}_{\text{org}}$ of -30 to -26‰ which cannot exclude abiotic Fischer-Tropsch synthesis	$\delta^{13}\text{C}_{\text{org}}$ of -30 to -23‰ lies within the range of biological fractionation
Interpretation	Abiotic artifacts created by the recrystallization of amorphous silica that displaced graphitic margins forming a spectrum of arcuate to dendritic artifacts	Silica permineralization of filamentous “microfossil” cells that could have included oxygen-producing cyanobacteria and possibly larger, beegiatocean microfossils

looked at the Raman spectra, carbon ultrastructure, and compared these to younger biogenic microfossils. Notably, a recent in-situ carbon isotope study found C-isotope heterogeneities within filamentous structures in the Apex chert and argued that this was compatible with a biogenic origin, and not an origin from a single remobilized hydrothermal (Fischer Tropsch) source (Schopf et al. 2018). However, given the complex multistage hydrothermal alteration history of the Apex Chert characterized by several workers, this could also explain the carbon isotope heterogeneities. In summary, the Apex Chert has proven to be a highly controversial, but also an instructive example of how the biogenicity and antiquity of microfossil-like structures can be tested.

Evidence for microbial life in a sub-seafloor environment may come from putative microfossils of the c. 3.24 Ga Sulfur Springs Group of the Pilbara, a volcanogenic, massive sulfide deposit, interpreted to contain pyritized filaments of thermophilic, chemotrophic prokaryotes (Rasmussen 2000 and Fig. 1f). These straight, curved, or sinuous filaments exhibit putative biological behavior including preferred orientations, clustering, and intertwining. They are found in an early chert fabric in a subsurface drill core that is cross-cut by later fractures thereby satisfying syngenetic requirements. A study of the

ultrastructure of these filaments found them to be comparable to pyritized Palaeoproterozoic *Gunflintia* microfossils, although abiotic origins could not be excluded, especially as the filaments were solid rather than hollow (Wacey et al. 2014).

Several putative examples of microfossils and microbial mats have been proposed from the Onverwacht Group of South Africa with a range of supporting evidence. These included filamentous, coccoid, and lenticular microtextures from the 3.43–3.41 Ga Kromberg-Chert based largely on petrographic evidence (Javaux 2019 and refs therein). Integrated C-isotope and ultrastructural data was not provided in these early studies and subsequent workers have emphasized the impact of hydrothermal fluid migration on these carbonaceous cherts, and the possible similarity to organics condensed onto volcanic particles (Wacey et al. 2018) thereby casting doubt on these microfossils. Stronger, evidence of silicified microbial mat remains has been presented from several other Onverwacht cherts summarized in (Lepot 2020 and refs therein) including: the 3.47 Ga Middle Marker Chert, 3.416 Ga Buck-Ridge Chert (Tice and Lowe 2004), and the 3.33 Ga Josefdal Chert. Key lines of evidence to support a microbial origin include rheological arguments based on the observation of plastically deformed, ripped-up organic fragments. Also, the

depth-controlled distribution of the various chert fabrics and carbonaceous microtextures found in, for example, the Buck Ridge Chert, that is consistent with a depth and light controlled ecosystem (Tice and Lowe 2004). It should be emphasized, however, that there is no compelling evidence of cellular preservation in these cherts, and that cell walls and cellular sheaths are not preserved, in other words these are not microfossils, rather laminated organic textures interpreted as microbial mat remains.

Intriguing large lenticular or spindle-shaped microstructures from the 3.4 Ga Strelley Pool Chert (Sugitani et al. 2015) and 3.0 Ga Farrel Quartzite of Western Australia have been proposed as microfossils. These structures are 20–100 μm across, lenticular in shape often with an equatorial flange, can form chains up to 7 individuals long, and have a central body that may contain vesicles and carbonaceous globules. Measurement of texture-coupled C isotope heterogeneities (Lepot 2020 and refs therein) also H/C and N/C ratios have been taken to support an origin for the microstructures from biological organic matter. It should be noted, however, that the same rocks can contain volcanic vesicles with organic and titaniferous coatings that must be carefully distinguished from the lenticular microfossils (Wacey et al. 2018). The exact biological affinity of these lenticular microfossils is not clear, whether they are large single cells or bacterial colonies as suggested by the reticulate wall of some examples (Javaux 2019). Large, hollow spherical organic-walled microfossils termed acritarchs, have also been described from siliclastic sediments of the ~ 3.2 Ga Moodies Group of S Africa (Javaux et al. 2010). These structures pass syngenicity and endogenicity tests and appear to be the oldest and largest organic-walled spheroidal microfossils reported to date and may represent stem-group eukaryotes, predating the currently recognized fossil record of crown-group eukaryotes by more than 1.5 Ga.

Stromatolites and Microbially Induced Sedimentary Structures

Stromatolites comprise laminated, centimeter to decimeter scale domes, cones, columns, and

planiform surfaces that are built through the interplay of physical, chemical, and biological processes. The first c. 2 billion years of the fossil record is dominated by stromatolites. The processes that lead to the growth of stromatolites and how these can be identified from laminar geometries and microfabric evidence are reviewed elsewhere in this volume. Here, a non-genetic definition of a stromatolite is adopted because it can be difficult to demonstrate active biological participation in stromatolite growth, especially in Archaean rocks where diagenetic recrystallization and low-grade metamorphism can overprint and destroy any organic microtextures that were once present. There have been many attempts to develop stromatolite biogenicity criteria (discussed elsewhere in this volume), and these will be discussed below, in an effort to distinguish laminated seafloor precipitates formed by purely chemical processes, from microbially mediated deposits.

Among some of the oldest and best-preserved Archaean stromatolites are coniform stromatolites of the 3.35–3.426 Ga Strelley Pool Chert of Western Australia. These were first proposed as biogenic in origin, although this was later rescinded by (Lowe 1994) because of the extreme continuity of the laminae, the absence of fine-scale “crinkly” laminae, the paucity of detrital material, lack of fenestrae or “gas bubbles” together with their evaporitic setting, which was argued to be more consistent with an abiogenic origin through chemical precipitation. Subsequent discoveries near the Trendall locality of large coniform stromatolites with rare branching on the flanks, also domal and laterally linked pseudocolumnar morphologies have supported biogenic interpretations, with these more complex morphologies being difficult to explain by purely abiotic processes (Hofmann et al. 1999). Improved characterization of the depositional environment and geological setting especially in the Panorama Belt of the North Pole dome, has led to the development of shallow-water to evaporitic carbonate platform depositional model for the Strelley Pool stromatolites (Allwood et al. 2018).

Slightly older, stromatolitic material comes from the 3.48 Ga Dresser Formation of the North

Pole Dome, which records an active volcanic environment with vigorous hydrothermal circulation forming complex barite-chert-carbonate deposits. These rocks have been the target of intense biosignature investigations on surface and drill core material that contain candidate stromatolites, microfossils, MISS, sulfur, and carbon isotope evidence, although many of these have been strongly debated. The stromatolite evidence comprises wavy-laminated convex-up precipitates of ferruginous carbonates that are variably silicified and contain sulfates (barite and gypsum pseudomorphs), and sulfides, the biogenicity of which has been debated based on morphological evidence (Lowe 1994). Moreover, the depositional environment has been variously interpreted as sub-seafloor hydrothermal “white smoker” type deposit, and more recently, as terrestrial hot-spring biogenic geyserite deposit (Djokic et al. 2017). Associated potential chemical biosignatures include heterogeneous sulfur isotope compositions of pyrite found in pyritized organic layers interpreted as derived from microbial mats, although a thermochemical origin could not be completely excluded (Lepot 2020 and refs therein), as is the challenge for many of the microscopic signatures in the Dresser Formation.

Older still, convex-up structures interpreted as stromatolites were described from metasediments of the Isua greenstone belt (Nutman et al. 2016) and are a cautionary example of how to employ strict biogenicity criteria. These structures occur in tightly folded rocks and comprise both convex-up structures adjacent to convex-down structures and therefore fail the requirements for syn-sedimentary structures with a predominance of convex-up morphologies and have thus been reinterpreted as deformation features (Allwood et al. 2018). In addition, the depositional setting of these rocks has been questioned, with geochemical signatures suggesting that the carbonate is more likely secondary in origin (metasomatic/metamorphic) and not shallow marine (Allwood et al. 2018).

In siliclastic rocks, especially sandstones and siltstones macroscopic evidence of life can be preserved by wrinkled bedding surfaces, tufted and dome-shaped structures interpreted to record

biostabilization of the sediments by microbial mats, and when a biogenic origin can be confirmed, these are termed microbially induced sedimentary structures (MISS). Some of the best-characterized examples come from the 3.22 Ga Moodies Group of South Africa that contain wrinkle structures, desiccation cracks, and roll-up structures that record the previous existence of microbial mats that effectively stabilized sediment on these ancient tidal flats (Noffke et al. 2006). Moreover, it has been shown that the distribution of the various MISS structures is tightly controlled by the changing shallow-water tidal to terrestrial deposition environment (Heubeck 2009). In the thin-section, the MISS preserve laminated carbonaceous fabrics that drape sand grains and preserve $\delta^{13}\text{C}$ isotope ratios that are consistent with microbial photosynthesis, which could be anoxygenic or possibly even oxygenic (Lepot 2020 and refs therein). Older possible MISS are described from the 3.48 Ga Dresser Formation of Western Australia described elsewhere in this volume.

Microborings

Microborings are micron-sized cavities created by the activities of rock-dwelling microorganisms termed endoliths. Undisputed fossilized examples come from 1.7 Ga silicified carbonates with downward-facing traces in stromatolitic laminae interpreted as cyanobacterial borings. On the early Earth, a sub-surface rock-dwelling mode of life may have offered many attractions, including: protection from more intense UV radiation and elevated impact-flux, proximity to geothermal heat, access to both oxidants and carbon sources carried by circulating fluids. Microorganisms that can adopt an endolithic mode of life include some cyanobacteria found in carbonates, also fungi that produce hyphae found in sandstones, and fractures in volcanic lavas. Traditionally, the sedimentary rock record has been the focus of efforts to find endolithic microborings, however, in the last 15+ years the discovery of microbial life in the modern sub-seafloor and associated microbial alteration textures has driven the search for endolithic microborings in Archaean lavas.

Microtextures argued to be mineralized endolithic microborings have been reported from the formerly glassy rims of pillow basalts and inter-pillow breccias from both South Africa (Furnes et al. 2004 and Fig. 1a) and West Australia (Banerjee et al. 2007). The original examples come from the ~3.46 Ga Hooggenoeg Complex of South Africa and are mineralized by titanite (CaTiO_3) found in a greenschist facies metamorphic mineral assemblage. These microtextures are 1–10 μm wide filaments, up to 200 μm long and extend away from “root zones” of fine-grained titanite that are associated with fractures in the original volcanic glass (Fig. 1a). Similar microtextures have been reported from inter-pillow breccias within the ~3.35 Ga Eurobasalt Fm of Western Australia. These are also infilled with titanite and were interpreted to have been formed by microbial tunneling on the seafloor that was subsequently infilled by the growth of metamorphic titanite. These microtextures have been questioned, however, with recent studies disputing both their syngeneticity and biogenicity (Grosch and McLoughlin 2014; McLoughlin et al. 2020).

Key findings that led to the refutation of Archaean titanite infilled microborings were the discovery from South Africa that these microtextures were not syngenetic to the Archaean seafloor (Grosch and McLoughlin 2014). In-situ U-Pb dating of the titanite found that the microtextures were 2.819 ± 0.2 Ga and therefore considerably younger than the 3.45 Ga eruptive age of the host pillow lavas. It was also found that the microtextures exhibit a morphological continuum and show a size distribution that is very different to that observed in modern seafloor lavas, being on average much thicker and showing a broader size range inconsistent with a biological population. Furthermore, the filaments are concentrated in a zone located within the contact aureole of a 2.913 ± 0.31 Ga sill (a younger intrusive body) and therefore an alternative abiotic origin, involving the growth of metamorphic titanite porphyroblasts in a thermal contact aureole was proposed (Grosch and McLoughlin 2014). In addition, quantitative microscale compositional mapping, combined with chlorite thermodynamic modeling of the greenschist facies matrix, revealed that the titanite filaments are

best developed in relatively low-temperature microdomains of the chlorite matrix, suggesting that they record retrograde cooling in the pillow lava host rock (Grosch et al. 2017).

Concerning, the Eurobasalt microtextures from Western Australia, reexamination of these titanite filaments, particularly focusing on their ultrastructure (McLoughlin et al. 2020), revealed new information that also questioned their origin and growth by the infilling of previously hollow microtunnels by titanite. Serial sectioning using FIB-TEM (focused ion beam, transmission electron microscopy) found that the microtextures were formed of discontinuous strings of titanite and anatase with coalescing crystallites forming the filaments. The TEM investigations also confirmed the absence of carbonaceous linings on the margins of the microtextures, previously argued to be the decayed remains of microbial cells. Considering the mineral assemblage found within the EuroBasalt metavolcanics, an alternative origin for the microtextures through the growth of titanite-anatase in an early seafloor-hydrothermal environment under fluctuating CO_2 - H_2O rich conditions has been proposed (McLoughlin et al. 2020).

In light of the reevaluation of candidate microbial microborings in Archaean metavolcanic glass described above, what then is the oldest fossilized microboring? An intriguing discovery comes from the 2.4 Ga Ongeluk lavas of the Transvaal Supergroup South Africa, and a study that reported branched filamentous microtextures in mineralized vesicles in the lava with morphologies suggesting an origin from fungal hyphae (Bengtson et al. 2017). These microfossils were interpreted to represent chasmoendolithic fungi dwelling in cavities in the lavas and may therefore represent a new type of evidence for life in the Proterozoic sub-seafloor.

Carbon Isotopes

One of the oldest claims for life comes from isotopically light carbon found in ~3.8 Ga rocks from the island of Akilia off the West coast of Greenland. The material analyzed was graphitic carbon found as inclusions within grains of apatite, with a $\delta^{13}\text{C}$ signature of -20 to -50%

(Mojzsis et al. 1996). The debate that has surrounded these observations provides an illustrative example of the need to understand the complete geological history of a rock argued to contain chemical traces of life. The original authors argued that this carbon was sealed within apatite grains from a low-temperature sedimentary environment and that the isotopic signature was indigenous and could be used as evidence to support life at ~3.8 Ga. A few years later, however, a different team examined the Akilia site and determined that the outcrop is not sedimentary. They found the outcrop to be purely metamorphic and argued that the carbon was also metamorphic in origin and thus of no biological relevance (Fedó and Whitehouse 2002). Several similar discussions have surrounded evidence of graphite from other Eoarchaeon and Hadean metasediments and zircon grains as reviewed by Lepot (2020); in these environments, metamorphic and metasomatic processes must first be rejected before biological possibilities can be explored.

In Mesoarchaeon rocks, combining in-situ measurements of C isotopes with texture-specific studies can be a powerful approach to testing biogenicity and exploring potential microbial metabolisms. Instructive examples described above, include the Strelley Pool lenticular microfossils, and disputed Apex-Chert microfossils (Schopf et al. 2018; Lepot 2020). In younger, Neoarchaeon rocks $\delta^{13}\text{C}_{\text{org}}$ values have been used in conjunction with other isotope systems especially, S, to explore the expansion of microbial metabolisms such as methanogenesis and acetogenesis, see below.

Sulfur Isotopes

In-situ studies of S isotope fractionations in Paleoarchaeon sulfides by (nano)SIMS (nanoscale-secondary ion mass spectroscopy) have found evidence of microbial sulfate reduction (MSR) which may have been either chemoautotrophic or heterotrophic. For example, microscopic sulphides contained within barite crystals in the ~3.49 Ga Dresser Formation of North Pole, Western Australia show multiple S isotope fractionations supporting the presence of MSR and microbial sulfur disproportionation

(Philippot et al. 2007). A heated debate has centered on the interpretation of the mass-independent S isotope fractionation (MIF) in these and rocks of similar age, centered on the contribution of abiotic, especially atmospheric, and thermochemical processes. However, the four S isotope patterns measured in the Dresser Formation are best explained by MSR. In slightly younger sedimentary rocks of the 3.4 Ga Strelley Pool Chert investigation of detrital and diagenetic pyrites also supports the operation of both MSR and microbial disproportionation in an open-marine, sedimentary-hosted ecosystem (Wacey et al. 2010). While sulfur isotope studies of a range of sedimentary and volcanic rocks from the Paleoarchaeon Barberton Greenstone Belt of South Africa (Grosch and McLoughlin 2013) have also found evidence of MSR, and the processes that control the mass independent fractionation (MIF) of sulfur appear to be different in the Barberton rocks compared to Pilbara.

Depletions in $\delta^{34}\text{S}$ in bulk sulphides are highly muted until c. 2.7 Ga interpreted to mean that MSR was only localized to an extent up until this time. In younger Neoarchaeon rocks, sulfur isotope evidence in conjunction with carbon isotopes (and sometimes rare earth element data) gives further insight into the emergence of sulfur metabolisms. For example, investigations of the 2.7–2.6 Ga Belingwe Belt of Zimbabwe have found pyrites in sulphidic shales with a wide range of $\delta^{34}\text{S}$ values from –21.1‰ to +16.7‰ that have been interpreted to indicate sulfate reducing and possible sulfur-oxidizing bacteria (Grassineau et al. 2001). Likewise, in-situ studies of the wide range in $\delta^{34}\text{S}$ of sulphides in lacustrine stromatolites from the 2.72 Ga Tumbiana stromatolites have been taken to support the presence of MSR, that combined with $\delta^{13}\text{C}_{\text{org}}$ values of –50‰ may indicate sulfate-fuelled anaerobic methanotrophy (Lepot 2020 and refs therein).

Future Directions

In the last decade, a clearer picture of the emergence of life in the Mesoarchaeon has appeared with several localities now providing robust

evidence of benthic and planktonic microbial life. This has been achieved through the refinement of biogenicity and syngenicity criteria; the discovery of new localities; the investigation of a wider range of rock types; and the application of high-resolution imaging combined with in-situ isotopic analyses. Many interesting questions still remain, especially concerning the timing of the appearance of different microbial metabolisms and in which geological environments they emerged. Taken together, our improved understanding of the earliest traces of life, along with the techniques and approaches developed, provides invaluable guidance for designing strategies to seek life elsewhere in our universe.

Pilbara craton · Barberton greenstone belt · Barite · Archean traces of Life · Drilling Project

Definition

During the past decade, several scientific drilling programs that have been carried out in Archean terrains. Other ones are planned in the near future. The aim of most of these drilling projects is to recover relatively well-preserved rock samples from below the present weathering profile and to obtain continuous rock cores that retain soft or friable units that outcrop poorly at the surface. Astrobiology-related studies such as search of pristine morphological or chemical traces of early life form an important part of these projects.

Overview

To date, in greenstone belts, both volcanic and sedimentary sequences have been targeted. The recovered cores have been analyzed to investigate conditions prevailing at the surface of the Archean Earth – the composition, temperature, and redox

state of the Archean ocean and atmosphere and the volcanic and sedimentary processes that operated early in Earth history – and, above all, to search for evidence of primitive life. The focus has been the ► [Pilbara Craton](#) in Western Australia, where four separate programs have been carried out, each involving collaboration between geologists from Australian universities, the Western Australian Geological Survey, and foreign agencies. The four programs are:

1. The Archean Biosphere Drilling Project (ABDP) cosponsored by several Japanese Universities,
2. The Deep Time Drilling Project (DTDP) of the NASA Astrobiology Institute
3. The Pilbara Drilling Project (PDP) of IPG Paris
4. The Dixon Island-Cleaverville Drilling Project (DXCL-DP) supported by the Japanese Ministry of Education, Culture, Sports, Science, and Technology (MEXT)

In South Africa's ► [Barberton Greenstone Belt](#), two French-driven drilling projects were completed to date:

1. The Barberton Barite Drilling Project (CNRS, IPGP) had the objective to obtain a representative sequence of black cherts, shales, tuffaceous sandstones and siltstones, jasper deposits, and bedded barite, which is a conspicuous assemblage of rock types typically observed from Early Archean seafloor hydrothermal settings. They well penetrated a section in the west limb of the Baryte Syncline to a depth of 182 m.
2. The Barberton Drilling Project (ICDP; July 2011–May 2012) included five diamond-core holes, each several hundred meters long. BARB-1 and BARB-2 targeted komatiitic rocks near Tjakastad in the southern part of the belt, whereas BARB-3 drilled 899.5 m through the Buck Reef Chert, both of the ► [Onverwacht Group](#). BARB-4 targeted turbidites and banded-iron formation and BARB-5 ► [barite](#), turbidites, and ► [spherules](#), both of the Mapepe Formation (lower Fig Tree Group). A total of 3052 m of core was recovered.

Two programs focused on the Archean-Proterozoic transition. After the Kola Superdeep Borehole (12,262 m deep), a series of short holes have been drilled in Russian Fennoscandia to sample the 500-million-year interval defining the Archean-Paleoproterozoic transition; the Agouron Griqualand Paleoproterozoic Drilling Project straddled a similar interval in the Northern Cape province of South Africa.

Definition

The term “Archean environmental conditions” refers to the geological, physical, and chemical conditions of the surface of the Earth during the ► [Archean eon](#). The surface of the Archean Earth was in many ways similar to that of today. Oceans likely covered most of the globe, but there were also regions of dry land. However, the oceanic crust was almost as thick as the ► [continental crust](#), mountain ranges were not very high, and parts of oceanic ridges and plateaus (thick piles of flat-lying lava flows) were

emergent. Geological processes such as volcanism, erosion, and sediment deposition operated but were influenced by a lack of vegetation, higher ocean temperatures, different water composition, and a hotter, more aggressive, acidic atmosphere. In addition, coastal settings may have been subjected to more intense reworking by high and more frequent tides.

Overview

The surface of the Archean Earth was in many ways similar to that of today. Oceans covered most of the globe, but there were also regions of dry land. The total area covered by oceans was greater than now for three reasons. First, the volume of continental crust may have been less, if continental crust indeed grew (progressively or in spurts) through time (Benn et al. [2006](#)). Second, the oceans might have been more voluminous because high temperatures in the mantle (Nisbet et al. [1993](#)) destabilized hydrous minerals and drove water to the surface. Third, oceanic crust was thicker. Its top lay at a shallower depth than today’s sea floor, thus displacing water which inundated low-lying margins of continents (Eriksson [1999](#)).

Mountain ranges existed but were not as high as those of today because the continental crust was heated internally and rendered more ductile by more abundant radioactive elements. Continental crust was relatively thin, while oceanic crust, produced by high-degree melting of the hotter mantle, was far thicker (Sleep and Windley [1982](#)). The subdued topography, the limited contrast between the thicknesses of oceanic and continental crust, combined with bigger oceans, meant that much of the continental crust was flooded (Arndt [1998](#)).

Just as during more recent geological history, global temperatures waxed and waned. The world’s oldest glaciation is reported from the 2.9 Ga-old Mozaan Group on South Africa’s Kaapvaal Craton (Young et al. [1998](#)) but on the whole temperatures appear to have been clement or high. The O and Si isotopic compositions of Archean ► [cherts](#) suggest that ocean temperatures

were commonly above 40 °C and possibly as high as 80 °C (Knauth and Lowe 2003). The atmosphere contained very little or no free oxygen but was richer in CO₂; rainwater was thus somewhat acid. Due to the absence of a protective ozone shield, UV flux at the Earth's surface was high. The atmosphere also contained SO and SO₂, causing sulfuric acid haze; haze from nitrous oxides and organics likely occurred as well. The normal cycle of erosion, transport, and deposition of sediment operated, but the rivers flowed through a landscape that was very different from that of today.

The feature that most starkly distinguished the Archean and modern land surface was the lack of vegetation. Microbes doubtlessly colonized the subsurface and constructed ► [biofilms](#) and thicker biomats which covered moist areas, possibly including low-lying fluvial floodplains, but most of the landscape likely had the appearance of bare rocks we see on recent Mars. The rate of weathering was enhanced by higher temperatures and a more aggressive atmospheric composition, possibly also by violent thunderstorms, but was slowed down by a lack of humic acid and thick soils that today greatly enhance weathering rates. These processes and rates are difficult to quantify. Erosion was likely enhanced by the lack of vegetation and thus lack of stabilized river banks, but restrained by the overall more modest mean elevation of continents. Active volcanism covered much of the surface with lava flows or pyroclastic deposits. The Moon, in a closer orbit and rotating faster about the Earth, caused higher and more frequent tides which may have raked the barren shorelines in much wider tidal belts than we see today.

The oceanic crust was composed of basaltic lavas like that of modern crust, but was more magnesian (picritic) in places (Sleep and Windley 1982). Parts of mid-ocean ridges and the summits of oceanic plateaus may have been emergent, forming what might be called “melano- (dark-colored) continents.” The pelagic sediment that covered this crust was different from that of today. An absence of shell-forming organisms precluded the formation of biogenic calcareous or siliceous oozes;

in their place occurred Si- or Fe-rich sediments that precipitated directly from the high-temperature seawater that contained high concentrations of these elements. Depending on the intensity of weathering of mafic material on exposed regions, much clay may have been produced, washed into the sea and deposited on oceanic crust. Hydrothermal venting of Si-charged seawater resulted in rapid silicification of most near-surface sediments and exposed igneous rocks, along with the formation of primary ► [cherts](#). Expulsion of fluids at hydrothermal vents led to the deposition of exhalative sediments, variably composed of sulfides, sulfates, carbonates or silica minerals (Russell et al. 2005).

The earliest Archean coincided with the end of the ► [Late Heavy Bombardment](#), a time of more frequent meteorite impacts. The largest of these would have vaporized parts of the oceans, raised oceanic and atmospheric temperatures significantly, and resurfaced parts of the Earth's surface. Whether their overall impact, in particular on the biosphere, was local or global, possibly extending to sterilization of Earth's surface environments, is debated (Abramov and Mojzsis 2009).

► [Precambrian](#)

Definition

The Archean (Archaean in British English) eon (the largest division of geological time defined in ► [stratigraphy](#)) is the second major period in geological history. Preceded by the ► [Hadean](#) eon and followed by the ► [Proterozoic eon](#), its beginning is usually taken as that corresponding to the age of the oldest preserved rocks, either the 4.0 Ga-old (Ga = 10⁹ years = billion years) ► [Acasta gneisses](#) (Canada) or the 3.85–3.80 Ga-old Amitsôq gneisses (Greenland).

Overview

The International Commission on Stratigraphy (ICS, July 2021) sets its beginning at the *Global Standard Stratigraphic Age* of 4.0 Ga, corresponding to the radiometric age of the gneiss of Acasta in Canada, though possible older rocks are those found in the ► [Nuvvuagittuq Greenstone Belt](#), Canada (4.3 Ga-old; O'Neil et al. 2008) (controversial). The transition to the Proterozoic is taken at 2.5 Ga (ICS, July 2021), which was thought to mark a major change in the Earth's geodynamic style and corresponds roughly to the ► [Great Oxygenation Event](#). The Archean eon thus encompasses an approximately 1.5-Ga-long period during which the oldest well-preserved rocks formed, and life likely originated. Together with the Hadean and the Proterozoic, it forms the supereon “Precambrian,” thence its synonym. Its tectonic style was different from today, with more abundant mantle plumes, greatly fragmented tectonic plates, and longer mid-oceanic ridges. The geochemical composition of some Archean rocks suggests plate tectonics could have started in this period that ► [plate tectonics](#) started in this period.

Geographical and Temporal Distribution of Archean Terranes

The Archean eon is characterized by the extraction from the mantle and the subsequent differentiation of significant amounts of ▶ [continental crust](#). Indeed, at the end of the Archean eon, probably about 75% of the juvenile continental crust had formed (e.g., Hawkesworth et al. 2020 for a review). Large parts of this Archean crust, named ▶ [cratons](#) or shields, have been preserved on all continents (Condie 1994; Fig. 1), including:

- In Europe, the 3.1–2.5 Ga-Baltic (sometimes referred to as Fennoscandian) and 3.8–3.2 Ga Ukrainian shields as well as a few outcrops in

northern Scotland (Lewisian gneisses in the Hebrides with a debated age of 3.52 ± 0.16 Ga)

- In Asia, the Siberian Aldan ▶ [Shield](#) (3.5–3.0 Ga), the Indian Dharwar (3.6–2.5 Ga), and the Sino-Korean cratons (3.8–3.0 Ga)
- In Australia, the Pilbara (3.6–2.5 Ga), Yilgarn (2.94–2.63 Ga), Gawler (2.5 Ga), and Northern Australia cratons
- In Antarctica, the Napier complex (orthogneisses dated at 3.95–2.46 Ga)
- In Africa, the Kaapvaal (3.6–2.5 Ga), Zimbabwe (3.5–2.5 Ga), and Madagascar cratons, as well as the Central and West Africa cratons

Archean Eon, Fig. 1 Distribution of Archean provinces (after Condie 1994; redrawn by Martin 1994). The exposed Archean terranes are in red, and the areas underlain by Archean rocks are in orange. (1) Baltic Shield; (2) Scottish Shield; (3) Ukrainian Shield; (4) Anabar Shield; (5) Baikal, Sayan, and Yienisei fold belts; (6) Aldan Shield; (7) Sino-Korean, Tarim, and Yangtze cratons; (8) Indian Shield; (9) Litchfield, Rul Jungle and Nanambu Complexes; (10) Pilbara block; (11) Yilgarn block; (12) Napier Complex; (13) Kaapvaal Craton; (14) Zimbabwe Craton;

(15) Zambian Block; (16) Kasāi Craton; (17) Central Africa Craton; (18) Ethiopian Block; (19) Chaillu Craton; (20) Cameroon N'tem Complex; (21) Man Shield; (22) Tuareg Shield; (23) Reguibat Shield; (24) Rio de la Plata and Luis Alves Massifs; (25) São Francisco Craton; (26) Guapore Craton; (27) Guiana Shield; (28) Wyoming Province; (29) Superior Province; (30) Kaminak Group; (31) Committe Bay Block; (32) Slave Province; (33) Labrador Shield; (34) Greenland Shield

- In South America, the São Francisco and Amazonian cratons (3.5–2.4 Ga) in Brazil and the 3.4 Ga Guyana Shield
- In North America, the Wyoming Province, USA (3.5–2.5 Ga); the Superior Province ((4.3)3.7–2.7 Ga); the Slave Province (dominated by 2.73–2.63 Ga greenstone sequences but with the ► [Acasta gneisses](#) dated to 4.03 Ga); the Labrador Shield (Canada) with the 3.9–3.7 Ga Iqaluk and Uivak gneisses of the Saglek-Hebron complex; and the Greenland Shield (3.8–2.6 Ga with older units at ► [Akilia](#) and Isua up to 3.88 Ga)

Among the Archean terrains older than 3.8 Ga, the largest continuous exposures are the Amitsoq gneisses in Greenland, which covers an area of 3000 km². The protolith of these rocks consists of older granitoids, metamorphosed into gneisses with emplacement ages of 3.822 ± 0.005 Ga. The oldest supracrustal rocks (volcaniclastic and sedimentary) are in Akilia island and the Isua supracrustal belt with older ages at 3.872 ± 0.010 Ga, together with banded iron formation of the Nuvvuagittuq greenstone belt (3.817 ± 0.016 Ga or older). The recognized oldest rocks on the Earth (covering a surface of about 20 km²) are the ► [Acasta gneisses](#) in Canada (Slave Province) with an age of 4.030 ± 0.003 Ga (Bowring and Williams 1999), while the oldest known minerals are the famous Jack Hills detrital zircons (Western Australia) with recorded ages as old as 4.404 Ga (Wilde et al. 2001). Similarly, inherited cores in zircons from Acasta provided an age of 4.20 ± 0.06 Ga (Iizuka et al. 2006). Other hadean zircons were reported in Brazil (Paquette et al. 2015) and in India (Miller et al. 2018). Recently, the short-lived ¹⁴⁶Sm–¹⁴²Nd isotope system yields an isochron suggesting an age of 4.13 Ga for the Ujaraaluk unit (amphibolite rocks), outcropping in the ► [Nuvvuagittuq Greenstone Belt](#) (O’Neil et al. 2012), though this age is strongly disputed and debated (Cates et al. 2013; Guitreau et al. 2013).

Geology of Archean Terranes

Archean terranes all show similar lithological associations, independent of their age: (1) granite-

gneiss, (2) ► [greenstone belts](#), and (3) late granitoids. In addition, some show a cratonal cover.

The granitic gneisses are the most abundant, composing up to 80% of the Archean continental crust. Better known under the acronym TTG for ► [Tonalite-Trondhjemite-Granodiorite](#) association (Jahn et al. 1981), these rocks are coarse-grained, gray orthogneisses (which means derived from magmatic rocks, in this case granitoids) with well-developed banding consisting of the alternation of whitish quartz-plagioclase layers with gray to black biotite- and amphibole-rich layers (Fig. 2). Contrary to typical modern granites, the TTG contains a very low proportion of potassic feldspar (KAlSi₃O₈).

The parent magma from which TTG derived results from the melting at high pressure of a hydrated mafic rock of basaltic composition (Fig. 3a). Indeed, when the pressure increases, basalt is transformed into amphibolite

Archean Eon, Fig. 2 Photo of typical gray gneisses (TTG) from Sand River, Limpopo, South Africa. These 3.283 ± 0.008 Ga-old rocks consist of the alternation of whitish quartz-plagioclase layers with gray biotite and amphibole-rich layers. (Photo H. Martin)

Archean Eon, Fig. 3 Pressure-temperature (P-T) diagram and schematic cross-section of both Archean (b) and modern (c) subduction zones. (a) The P-T diagram shows the dry and 5% hydrous solidus of tholeiite as well as main dehydration reactions of the oceanic lithosphere. Abbreviations: H is hornblende out, A is anthophyllite out, C is chlorite out, Ta is talc out, Tr is tremolite out, Z is zoisite out. G outlines the stability field of garnet. The blue field is the P-T domain where slab melts can coexist with hornblende- and garnet-bearing residue. In the Archean (inset b), the geothermal gradient along the Benioff plane

was very high; the subducted slab melted at shallow depth before dehydration could take place. After 2.5 Ga, Earth was cooler and the geothermal gradient along the Benioff plane was lower (inset c) such that slab dehydration generally occurred before its melting began. The liberated volatiles (mainly water) ascended through the mantle wedge, thus lowering its solidus temperature, which induced its melting. Abbreviations: CO is oceanic crust, CC is continental crust, sm is solidus of hydrated mantle, and red teardrops indicate magma

(amphibole $\pm$ garnet $\pm$ plagioclase feldspar-rich rock) and then into eclogite (pyroxene + garnet rock). These products melt to give the parental magmas of TTG (e.g., Martin and Moyen 2002). Although all geologists agree on the basaltic source of TTG, the geodynamic environment where melting took place is still debated: (1) $\blacktriangleright$ **basalts** from a subducted oceanic crust (Fig. 3; Martin 1994; Martin and Moyen 2002); or (2) underplated basalts melted during the passage over a mantle plume (Smithies 2000). The first hypothesis appears realistic since the Archean heat production was several times greater than today. This assertion is inferred by the genesis of high-temperature (Mg-rich) magmatic rocks called $\blacktriangleright$ **komatiite**, during the Archean, which require a mantle 100–350 °C hotter than today (e.g., Arndt et al. 2008). It is also consistent with the subduction of young and consequently hotter oceanic plates.

In modern tectonic regimes, the subducted plate is old and cold, such that it dehydrates during its descent into the mantle. Volatiles, mainly water, are liberated and ascend through the mantle

wedge, lowering its melting temperature (the mantle wedge lies between the descending or subducting oceanic plate and the continental (or oceanic) plate). Mantle wedge melting generates magmas with andesitic to granitic compositions that are accreted to form new continental crust (Fig. 3b). Modern subduction systems (both mantle and oceanic crust) are normally too cold to allow the subducted basalt to melt. If a hotter Archean mantle associated or not to the subduction of a younger oceanic crust is assumed, then the latter cannot rapidly dehydrate and direct melting of hydrated basalts is possible, resulting in TTG magma genesis (Fig. 3c).

$\blacktriangleright$ **Greenstone belts** represent only 5–10% of the Archean terrains. These elongated structures (typically $>100 \times 20$ km) contain variable amounts of metamorphosed mafic to ultramafic volcanic sequences associated with sedimentary rocks. The name “greenstone” comes from the green hue imparted by the color of the metamorphic minerals within the mafic rocks. Chlorite, actinolite, and other green amphiboles are the usual green minerals. In some cases, greenstone

belts show a specific stratigraphic sequence, with ultramafic lavas (komatiites) at the base of the sequence, followed by basalts (often erupted under water with typical pillow structures). Variably metamorphosed sedimentary rocks (► [metasediments](#)) are emplaced at the top of the sequence. Greenstone belts are in complex contact relationships with adjacent plutons or metamorphic rocks: commonly, the contacts are structurally modified (thinned or thickened) contact-metamorphism aureoles; brittle-ductile fault planes are also common.

► [Komatiites](#) are ultramafic volcanic rocks (Arndt et al. 2008), almost exclusively restricted to the Archean eon, which are distinguished from the more common basalts by a higher content of MgO ($\geq 18\%$) and low content of most of the other elements. The high Mg content is explained by a higher degree of melting of the mantle; the melting temperatures of komatiites range between 100 °C and 1650 °C (Arndt et al. 2008) compared to 1100–1300 °C for modern basalts. Their occurrence demonstrates that the internal Earth heat production in the Archean was higher than today. After emplacement, these magmas cooled very rapidly, resulting in acicular and dendritic textures of olivine or pyroxenes phenocrysts, referred to as “spinifex” textures, which are typical of komatiites. Earth almost totally ceased to produce komatiites after 2.5 Ga. Archean mafic volcanics were mainly tholeiitic basalts (Fig. 4), while calc-alkaline lavas, in particular andesite, were rare. At the top of the sequence, more felsic rocks (dacites to rhyolites)

can occur interbedded within the sedimentary successions.

Sedimentary successions include thick lithic sandstones (also called litharenites which are sandstones containing more than 25% detrital rock fragments, and more rock fragments than feldspar grains) deposited in deep water as ► [turbidites](#) (Fig. 5) and in subordinate order, conglomerates. Well-preserved 3.5 Ga-old turbidites can be observed in the Komati River valley of the ► [Barberton Greenstone Belt](#), South Africa. They are overlain by and interbedded with siltstones, shales, ► [chert](#), and ► [banded iron formations](#) (BIF; Fig. 6). Cherts and BIF are common lithologies in Archean greenstone belts and are likely the result of intense hydrothermal activity

Archean Eon, Fig. 4 Pillow lavas of 2.65 Ga-old tholeiitic basalt from Kuhmo (Finland). (Photo H. Martin)

Archean Eon, Fig. 5 Clastic sediments (conglomerate) from the base of the 3.22 Ga-old Moodies group, Barberton, South Africa. (Photo H. Martin)

Archean Eon, Fig. 6 Banded Iron Formation (BIF) from Copping Gap (Australia). These rocks consist of alternating silica- and iron-rich layers. (Photo H. Martin)

Archean Eon, Fig. 7 Dyke of high-Mg granodiorite (sanukitoid) intrusive into the 2.65 Ga-old Kuhmo greenstone belt (Finland). (Photo H. Martin)

on the ocean floor (Westall 2005; Van Kranendonk 2006).

Both the TTG basement and the greenstone belts were later intruded by high-Mg granitoids or sanukitoids (Fig. 7). These calc-alkaline granites are rich in potassic feldspars and magnesium. They might have derived by melting of a mantle peridotite, whose initial composition was modified by assimilation of TTG (Martin et al. 2009).

Archean Geodynamics

Modern plate tectonics induces horizontal forces that cause thrusting during orogenesis. These structures are known in most Archean terranes, indicating that tectonic forces similar to those controlling movement of modern tectonic plates could have operated since at least 3.8 Ga ago. However, Archean terranes also show large evidence of major vertical deformation that produces dome-and-basin structures (Fig. 8), which are exclusive to the Archean eon. This type of tectonics is driven by gravity (as opposed to plate tectonics which is driven by mantle convection) and this process has been known as sagduction since the 1970s (Gorman et al. 1978). Sagduction structures result from the down motion of high-density greenstone terranes (such as komatiites; density = 3.3 g/cm^3) into the TTG basement (density = 2.7 g/cm^3) and the concomitant upward motion of low-density TTG into the greenstones creating inverse diapirs. At the top of the inverted diapirs, a basin is created allowing deposition of sedimentary rocks. Several authors

have suggested that horizontal forces acted mainly at the plate boundaries (as today) while sagduction processes were concentrated within plates.

Another difference compared with today is the supposed length of the mid-ocean ridges, that is, the divergent boundaries between two tectonic plates, where new oceanic crust is produced. Indeed, the large amounts of internal heat produced during the Archean eon had necessarily been released to the surface. Otherwise, the accumulated heat should have resulted in melting the external part of our planet, which is not attested by the geological record. Heat was certainly greater in those remote times than today because the latent heat of accretion and the heat derived from the radioactive decay of elements such as U, Th, and K, present in higher amounts (e.g., the uranium stock on Earth in the Hadean was twice the present-day one). As conduction is not efficient to evacuate the internal heat, Archean convection should have played this role and, as today, heat must have been released through the mid-ocean-ridge systems. As the amount of heat to evacuate was greater, it can be concluded that the excess of heat has been released through convective processes. Convection rate could have been slightly greater, but mainly the ridge length was significantly greater than today. Indeed, the amount of heat dissipated is correlated with the cubic square of the ridge length (Hargraves 1986). Because the Earth volume and surface did not significantly change since 4.5 Ga, it means that a greater ridge length was present to evacuate the larger amount of heat. In turn, a longer ridge system results in smaller tectonic plates (Fig. 9). Today, mid-oceanic ridges are the place of an intense hydrothermal activity, which is attested by the presence of black and white smokers. If the total ridge length was greater in the Archean, the hydrothermal activity should also be more vigorous; which is corroborated by the great abundance of hydrothermal cherts in all terrains older than 2.5 Ga.

Hydrosphere, Atmosphere, and Climate

There is good evidence that oceans were present on the Earth already in the early Archean (~ 3.8 Ga ago) after the ► **Late Heavy Bombardment** (Abe

Archean Eon, Fig. 8 (Left) Sketch depicting the three main steps of sagduction: (1) In a greenstone belt, high-density komatiites ($d = 3.3 \text{ g/cm}^3$) emplace over lower-density ($d = 2.7 \text{ g/cm}^3$) TTG basement rocks, thus generating an inverse density gradient; (2) komatiites sink downward into the TTG basement, which favors a relative upward motion of the TTG; (3) the movement is amplified

creating a sedimentation basin at the center of the greenstone belt. Green is komatiites, pale yellow is TTG basement, and yellow gold is sediment. (Right) Satellite photo of the sagduction structures at the Pilbara craton, Western Australia. The greenstone belts (in dark green and black) are localized between TTG domes (yellowish). The width of the photo is $\sim 300 \text{ km}$

Archean Eon, Fig. 9 Sketch representing the size of the tectonic plates that presently cover the surface of the Earth (left) and that supposed for the Archean plates (right)

1993; Sleep et al. 2001), and possibly during most of the Hadean (e.g., Mojzsis et al. 2001; Wilde et al. 2001; Martin et al. 2006). The convincing evidence comes from one of the oldest areas of volcanic and sedimentary rocks on Earth – the ► **Isua**

Supracrustal Belt, Southwest Greenland. The ages of the rocks have been established at about 3.7–3.8 Ga. In the Isua Supracrustal Belt, pillow basalts provide evidence of underwater eruption and metasedimentary rocks (banded iron

formations, metapelite, and ferruginous quartzite) are the products of erosion, fluvial transport, and subaqueous deposition (Rosing et al. 1996).

Primary fluid inclusions were found in quartz crystals in iron oxide structures from the 3.5 to 3.2 Ga ► [Barberton greenstone belt](#), South Africa (Channer et al. 1997), intra-pillow quartz from the Dresser Formation (3.49 Ga), ► [Pilbara craton](#), Western Australia (Furiel et al. 2004; Marty et al. 2018), and in the 2.7 Ga Abitibi Greenstone Belt, Ontario, Canada (Weiershauser and Spooner 2005). The analysis of major cations and anions indicates that the chemistry of the seawater was like today, but with some noticeable differences in iron, iodine, and bromine abundances indicating a larger influence of hydrothermal fluids (today, the chemistry of seawater is mainly controlled by weathering of continents with a minor role for hydrothermal fluids). Salinity was basically NaCl-dominated, though salinities up to ten times the present values have been measured, possibly related to seawater evaporation in closed basins (Furiel et al. 2004).

The secondary atmosphere of the Earth in the Archean was possibly mildly reduced. It was likely composed of N₂ and CO₂, with other gases (Ar, CH₄, H₂O, etc.) in minor amounts as observed today in the primitive atmospheres of Venus and Mars (Pinti 2021). The amount of N₂ was possibly close to the present level (Kasting 1993; Marty et al. 2013; Som et al. 2012) though it has been suggested that could have been as high as 2–3×, the present-day level (Wordsworth and Pierrehumbert 2013). The CO₂ concentration might have been up to 1% in volume or higher (Kasting 1987), while oxygen was likely ~1 parts per million by volume (ppmv) against the 21% today. Oxygen concentrations rose only at the end of Archean to values close to 1% of their present-day level, probably because of shifts in the competition between the production of oxygen derived from cyanobacteria photosynthesis and the rate of consumption of oxygen by reductants such as volcanic gases (e.g., Kump and Barley 2007). The amount of CO₂ in the atmosphere is still a matter of debate, but the occurrence of larger amounts of greenhouse gases (CO₂, CH₄) may have been needed in the Archean atmosphere to counterbalance the lower radiation from the

faint young Sun, which was ~30% less than the present-day value (Kasting 2010). Archean terranes do not contain evidence for major glaciations during the first two billion years of the Earth's history indicating that a warmer climate (as suggested by high ocean temperatures; Robert and Chaussidon 2006) dominated during the eon.

Traces of Life

Though the timing of the origin of life is unknown, the Archean world likely saw the emergence of the first organisms. Several morphological, molecular, and chemical traces of life punctuate the Archean sedimentary record. Currently, it is difficult to declare with certainty what the oldest trace of life is, and importantly what its nature and habitat were. Life can be traced unambiguously to approximately 2.7–3.0 Ga ago (Lopez-Garcia et al. 2006). Beyond this point, many claims for biological processes have been made, and all of them have to some degree been questioned. Some of the intriguing but controversial early Archean traces include (1) isotopically light graphite inclusions in rocks older than 3.8 Ga from Akilia island and the Isua Supracrustal Belt in southwest Greenland (Mojzsis et al. 1996; Van Zuilen et al. 2002); (2) kerogenous microstructures, stromatolites, and diverse stable isotope ratio anomalies in 3.5 Ga cherts from the Pilbara Granitoid-Greenstone Belt in Western Australia (Schopf 1993; Brasier et al. 2005; Ueno et al. 2006; Pinti et al. 2009) (Fig. 10); (3) kerogenous

Archean Eon, Fig. 10 3.5 Ga-old stromatolites from the North Pole (Pilbara, Australia)

microstructures, stromatolites, and diverse stable isotope ratio anomalies in cherts, as well as microscopic tubes in altered pillow basalts from the 3.4 to 3.2 Ga Barberton Greenstone Belt in South Africa (Staudigel et al. 2008); (4) in the Saglek-Hebron gneiss complex, based on carbon isotopic signatures of graphite and carbonates found in 3.95 Ga-metasedimentary rocks (Tashiro et al. 2017); (5) micrometer-scale hematite tubes and filaments – with morphologies similar to those of filamentous microorganisms from hydrothermal vent precipitates – found in BIFs from the Nuvvuagittuq Greenstone Belt (Dodd et al. 2017).

Basic Methodology

The knowledge of the primitive Earth has improved notably in the last 20 years, thanks to extensive U-Pb zircon geochronological studies which allowed identify new fragments of ancient cratons of the Archean age or even Hadean. Exposure of these terranes and the petrogenetic study of rocks by radiogenic and stable isotopic techniques are improving the general knowledge on the geological evolution of the ancient cratons. In particular, application of short-lived nuclides, such as $^{146-147}\text{Sm}$ - $^{142-143}\text{Nd}$, are evidences that Archean cratons could be the product of reworking of even older Hadean (≥ 4.2 Ga) mafic crust (e.g., O'Neil and Carlson 2017), pushing back in time the beginning of the differentiation of the continental crust, and possibly of potential habitats for primitive forms of life.

Key Research Findings

1. Most Archean terranes are composed of ► **Tonalite-Trondhjemite-Granodiorite** rocks (or TTG) of intermediate-felsic composition. Contrary to typical modern granites, the TTG contains a very low proportion of potassic feldspar. The parent magma from which TTG derived results from the melting at high pressure of hydrated basalts. The closest modern analogues of TTG are adakite that form in “hot

subduction” environment, that is, by melting of the basaltic oceanic crust subducting at low angle and thus reaching rapidly high temperatures able to melt the oceanic hydrated crust. Generation of TTGs suggest the occurrence of plate tectonics similar to the modern one;

2. Numerous Archean cratons show dome-and-basin structures suggesting vertical forces acting on the continental plates. This phenomenon called sagduction results from the down motion of high-density greenstone terranes composed of komatiites into the lighter TTG basement and the concomitant upward motion of low-density TTG into the high-density greenstones creating inverse diapirs. To reconcile these structures with the TTGs genesis in subduction-related environments, it has been suggested that horizontal forces acted mainly at the plate boundaries (as today) while sagduction processes were concentrated within plates;
3. The Archean mantle was 100–350 °C hotter than today as inferred by the occurrence of komatiite, high-temperature (Mg-rich) magmatic rocks typical and exclusive of the Archean eon, and TTGs which required a hotter mantle around subduction zones;
4. To dissipate the latent heat of accretion and higher heat fluxes provoked by decay of higher amounts of radioactive elements present in the crust than today, it has been suggested that mid-ocean ridges were longer and consequently tectonic plates, smaller than the present-day ones;
5. Occurrence of marine sediments such as turbidites and banded iron formation indicate that water environments were abundant in the Archean eon, where first life forms could have evolved; even if the origin of first micro (pseudo)fossils is largely debated, stromatolite forms in the Pilbara terrane of Australia strongly suggest that a biosphere was present.

Applications

The study of the Archean eon is extremely important because there are evidence of a planet progressively evolving towards geological

complexity: a continental crust formed and differentiated from primitive Hadean mafic crust; modern-like plate tectonics developed, contributing to exchange volatiles, metals, and other elements between the interior to the surface, possibly furnishing potential nutrients and energy fluxes to developing prokaryotic form of life; atmosphere-ocean system likely modified its chemistry towards less aggressive environments (lower salinity, acidity, etc.) preparing to its major change at the end of the eon, its oxygenation.

Future Directions

There are numerous open questions on the geological evolution of Archean environments and potential habitats for life. Likely, research is moving in two main directions: (1) try to answer the still very much debated question, when and how modern-like plate tectonics started? (2) are there surface environments sufficiently preserved from geological and tectonic forces that could have preserved pristine forms of life that could help in rebuilding back the tree of life on our planet?

Archean mantle · Convection · Archean thermal regime · Continental crust extraction · Oxidation state

Definition

Archean mantle refers to the terrestrial mantle during the Archean eon, which differed both physically and chemically from the modern-day mantle.

Overview

The mantle is that part of Earth or other planets which is between the ► [crust](#) and the core. The upper mantle, from the base of the crust at about 9 km (oceanic) or 30 km (continental) to the transition zone at 660 km, is composed mainly of ► [peridotite](#), an ultramafic rock mainly composed of ► [olivine](#) ((Mg,Fe)₂ SiO₄), pyroxene ((Mg, Fe, Ca) SiO₃), and minor garnet ((Mg, Fe, Ca)₃ Al₂ (SiO₄)₃). In the lower mantle, which extends to the core at 2990 km, the minerals are mainly Mg- and Ca-perovskite ((Mg,Ca)TiO₃) and magnesio-wüstite ((Mg, Fe)O). The mantle is solid except for localized zones of partial melting, but it convects with velocities of a few tens of centimeters per year.

The Archean mantle differed from the modern mantle in several important ways. Because the main sources of heat – ► [radioactivity](#), residual heat from accretion, and core crystallization – were more active than today, the mantle was hotter and it convected more vigorously. Higher temperatures in mantle upwelling beneath ► [mid-ocean ridges](#) produced larger melt volumes and a thicker oceanic crust. Higher temperatures at depth may have resulted in larger and hotter mantle plumes. The abundance of ► [komatiite](#) only in the Archean provides evidence of higher mantle temperatures.

The composition may also have been different, if, as many authors believe, the continental crust was less voluminous through the Archean. Continental crust contains far higher concentrations of elements such as Si, Al, K, and the “incompatible” trace elements, and the segregation of this crust has left the upper part of the modern mantle depleted in these elements. If crustal growth were incomplete in the Archean, either the volume of depleted mantle or the degree of depletion would have been less. The isotopic composition of rocks from the Archean mantle should, in theory, cast some light on the problem but at present, the message is ambiguous. The Hf isotope compositions of zircons show evidence of extraction prior to 4 Ga ago of enriched material, perhaps continental crust; the Nd isotopic compositions of rocks from the oldest areas of West Greenland have been interpreted to indicate derivation from strongly depleted mantle. Either these rocks were extracted from a small and localized volume of mantle or a large volume of continental crust had formed at this time.

If the mantle was significantly hotter, it would have been drier because the reactions that liberate water in upwelling mantle, where degassing takes place, or in subduction zones, where the mantle is rehydrated, are temperature-dependent. The proportion of water on the surface was larger and therefore the volume of the oceans may have been greater. The oxidation state of the Archean mantle has been investigated using redox-sensitive elements such as vanadium; no significant difference from that of the modern mantle has been established.

Definition

Archean tectonics is the study of the formation, interaction, and deformation of the Earth's continental and oceanic crust during early Earth history (the Archean Eon; ca. 4.0–2.5 Ga) and the driving forces behind these processes, including mantle plumes, subduction, and accretion/collision. This topic remains highly controversial due, in part, to a fragmentary rock record, but also to nonunique interpretations of complex geological datasets in the absence of actualistic plate configurations. Historically, Archean tectonics has been polarized into uniformitarian (i.e., analogous with modern, or Phanerozoic Earth) and non-uniformitarian views, but recent studies have favored modern

Earth processes in the Archean, complicated by problems arising mainly from greater heat production and higher mantle temperatures (Condie 1994; Benn et al. 2006; Brown and Rushmer 2006). The discussion revolves around the basic question if and how tectonics in the Archean was different from modern-style plate tectonics.

History

Although the relative antiquity of some parts of the continental crust was recognized more than 150 years ago (Logan 1857), it was not until the advent of radiometric dating, 100 years later, that the antiquity of much of the continental crust was fully appreciated (Stockwell 1961). Only in the past decade it has been discovered that the preserved crustal record on Earth extends back to within 150 Ma of the age of formation of the Solar System (Wilde et al. 2001). Early geological studies found that continental crust older than about 2.5 Ga was different from younger crust. Archean crust showed distinct regional patterns defined by overlapping, elliptical areas of granitic rocks (gregarious batholiths; Macgregor 1951); steeply dipping, generally synclinal, greenstone keels (granite-greenstone crust: Hickman 1984; Chardon et al. 1996); and a unique type of ultramafic lava known as ► [komatiite](#) derived from high-temperature mantle melts (Viljoen and Viljoen 1969; Arndt 2003). Many authors also noted that Archean granite-greenstone crust lacked the diagnostic features of modern subduction/collision zones, including accretionary tectonic mélange, ophiolites, and high-pressure/low-temperature metamorphism, leading some to suggest – even recently – that plate tectonics either did not operate in the Archean (Hamilton 1998; McCall 2003; Stern 2005) or operated in conjunction with other processes (e.g., Rey et al. 2003; Sandiford et al. 2004).

Overview

The Archean ► [mantle](#) was probably 100–300 K hotter than today, which significantly affected the

dominant tectonic style. Geochemical, geophysical, and modeling evidence suggests some form of ► [plate tectonics](#) in the Archean, although the absence of key characteristics such as ophiolites and blueschists implies that it probably differed from modern ► [plate tectonics](#). Evidence for Archean plate tectonics was recognized quite early on in the type of Archean ► [crust](#) known as high-grade gneiss terranes. This evidence included the presence of large-scale recumbent isoclinal folds associated with crustal thickening (Bridgwater et al. 1974; Myers 1976; Wilks 1988; Hanmer and Greene 2002), voluminous sodic granitoids derived from high-pressure melting of basalt (Martin et al. 2005; Rapp et al. 1991), high-pressure metamorphism (Riciputi et al. 1990; Harley 2003), and structures consistent with terrane accretion (Nutman et al. 2002; Windley and Garde 2009). Over the past three decades, abundant evidence for Archean plate tectonics has also been found in some Archean granite-greenstone terrains in the form of thrusts and recumbent isoclinal folds, coupled high-pressure-low-temperature metamorphism, fossil subduction zones, accreted terranes, rift sequences, and subduction-zone magmatism (Card 1990; Heubeck and Lowe 1994; Calvert et al. 1995; Smithies et al. 2005; Moyen et al. 2006; Wyman et al. 2006; Van Kranendonk 2007; Van Kranendonk et al. 2010). However, an absence of hallmark characteristics of modern subduction-accretion zones in many granite-greenstone terrains (Hamilton 1998; McCall 2003; Stern 2005), the autochthonous nature of some major greenstone successions, and suggestions that mantle roots form through in situ melting events rather than through subduction stacking indicates local crustal development as volcanic plateaus developed on top of older continental basement (e.g., Blenkinsop et al. 1993; Bleeker et al. 1999; Van Kranendonk et al. 2007). Indeed, many studies suggest that some pieces of Archean crust contain features that cannot be ascribed to uniformitarian, Phanerozoic-type, plate tectonics, but rather formed as a result of large-scale intra-crustal differentiation accompanying periods of mantle-plume-related magmatism (Stein and Hofmann 1994; Whalen et al. 2002; Rey et al. 2003;

Smithies et al. 2009; Van Kranendonk et al. 2009). The fact that different processes have been recognized from studies of different pieces of Archean crust indicates that there was no single Archean tectonic process, but rather that – as with modern Earth – Archean continental crust formed through a variety of processes, including plate tectonics and mantle-derived upwellings, and probably through the interaction between these two end-member processes.

Basic Methodology

Direct field evidence from Archean continental lithosphere provides a record of Archean tectonic processes. Geophysical methods include paleomagnetism and seismic evidence. Solidifying magma registers the paleo-latitude and thus can record (relative) continental motion. Seismic profiles through Archean crust indicate the presence of dipping seismic reflectors, which could be interpreted as the remnants of a fossil subduction zone. Among the geological evidence, ophiolites (slivers of oceanic lithosphere that escaped subduction), blueschists, and ultrahigh-pressure metamorphic rocks (partly subducted rocks that emerged again at the Earth's surface) are all well-understood features associated with modern plate tectonics. Their occurrence throughout Earth's history is thought to provide clear indicators of plate-tectonic activity. Large-scale tectonic structures can be indicative as well: linear structures are often interpreted as remnants of subduction trenches, whereas large oval-shape structures are thought to be diapir- or dome-related that might not need any plate-tectonic activity.

Geochemical and petrologic techniques provide the “fingerprints” of the chemical processes associated with Archean tectonics. Mantle melting will deplete the mantle of “incompatible” elements (Rollinson 2007). Another form of element separation occurs due to differences in fluid mobility, so that some elements will preferentially move with any pore fluids, while others will stay in the residue. These processes will leave geochemical fingerprints that can be used to recognize ancient subduction processes (e.g., Shirey

et al. 2008). In addition, geochemical dating of crustal rocks and mantle material shows how mantle material was depleted through time by continent formation. Since continents today are formed primarily at subduction zones, this has been interpreted as another indication for the presence of ancient subduction and therefore plate tectonics.

Various modeling techniques are used to further constrain the range of dynamically viable tectonic processes during the Archean. Tectonic vigor is related to mantle convection and intimately couples to the cooling rate of the Earth: tectonic activity leads to increased heat loss from the mantle, and mantle temperature influences the vigor of tectonic activity. Mantle temperature through time therefore provides an important constraint, and parameterized and numerical modeling techniques provide a means to link mantle temperature and tectonic activity. Today's plate tectonics is primarily driven by the subduction process, and subduction dynamics is, to a large extent, influenced by mantle temperature due to melting events and the temperature-dependent strength of the lithosphere. The viability and style of subduction in an early, hotter Earth is investigated using parameterized and numerical modeling techniques.

Key Research Findings

Field evidence has been used to argue for or against modern-style plate tectonics in the Archean. Ophiolites are preserved pieces of old oceanic lithosphere that escaped subduction, and the occurrence of old ophiolites is therefore a clear indicator of plate-tectonic activity. They are widespread since ~1 Ga, but are much rarer before that. Recently, Furnes et al. (2007) reported a 3.8 Ga-old ophiolite in Isua, West Greenland, although their interpretation has been disputed. Other direct types of evidence for plate tectonics are blueschists and ultrahigh-pressure metamorphic rocks, which are both generally believed to form within subduction zones, where they are brought down to large pressures and temperatures, and subsequently make it back to the surface. The

oldest blueschists are ca. 850–700 Ma old, while the oldest UHP localities are ~600 Ma old. These data could indicate that modern-style plate tectonics did not start until the Neoproterozoic (Stern 2005) or that the appearance of plate tectonics evolved over time (van Hunen and van den Berg 2008).

Earth's thermal evolution provides further constraints. Today, plate tectonics forms the dominant cooling mechanism for the Earth and is therefore closely linked to the thermal evolution of the Earth. The Archean Earth had an amount of radiogenic heat production two to three times larger than today due to the gradual decay of the dominant heat-producing elements uranium, thorium, and potassium in the mantle. Today, the surface geothermal heat flux (heat escaping the Earth's interior) is ~30% provided by internal radiogenic heating while the remaining 70% comes from cooling of the Earth (Turcotte and Schubert 2002; Korenaga 2006). This shows that surface heat flow from radiogenic heating was a lot more important in the Archean which implies that either surface tectonics were such that the total surface heat flux was higher or that Earth was not cooling (significantly) or was perhaps even heating up. Inferred liquidus temperatures from ophiolites and greenstone belts suggest a gradual mantle temperature drop of ~200 K since the Archean. Komatiitic melt data suggest a mantle potential temperature (i.e., mantle T extrapolated to surface P , T -conditions) reduction by ~300 K for dry melting to ~100 K if melting took place under much wetter conditions. Jaupart et al. (2007) provide a recent overview of the thermal evolution of the Earth.

The dynamical viability of subduction in the Archean has been questioned. Today, plate tectonics is primarily driven by dense slabs sinking into the mantle, and thereby pulling the trailing lithosphere across the surface. Archean plate tectonics would require a similar driving mechanism. A hotter mantle provides more melt and therefore a thicker, low-density mafic crust (up to 20 km thick instead of today's 5–8 km) that doesn't easily subduct. Although dehydration during melting will make the plate compositionally stronger and could allow for similar plate-tectonic rates in the Archean as today (Korenaga 2006), thermal weakening would probably dominate if the mantle

was substantially hotter and would result in weaker plates. The combined buoyancy and plate strength effects make subduction inefficient for mantle temperatures more than 150 K hotter than today (van Hunen and van den Berg 2008).

Today's continental crustal rocks (loosely termed andesites) differ significantly in trace-element composition from their Archean counterparts (trondhjemite-tonalite-granodiorite, or TTGs). Whereas andesites are thought to ultimately derive from melting in the hydrated supra-subduction mantle wedge, TTGs seem to form from wet melting of oceanic basalts at sometimes >50 km depth, and the most popular formation model is melting of subducting oceanic crust (Foley et al. 2002). So the differences between modern and Archean continental crust suggest a secular evolution of the subduction process. But at the same time, it indicates the need for a process to bring fluids to 50–100 km depth throughout the Earth's history. At present, no other mechanism than subduction seems capable of doing that, which is regarded as one of the strong arguments in favor of Archean plate tectonics.

However, although most studies support Archean plate tectonics, perhaps in some modified form, the possibility of other dominant tectonic processes should not be excluded. If indeed plate tectonics were absent in the Archean, such alternative tectonic models were probably essential to provide a mechanism for the observed steady mantle cooling of 50–100 K/Gyr. One popular model is the crustal delamination model (e.g., Zegers and van Keken 2001), in which mantle melting events would thicken the continental crust until its base becomes gravitationally unstable and would cause lithospheric overturn. Such models would explain observations from early Archean rocks such as the ovoid-shaped intrusions in the eastern Pilbara craton.

Applications

The style and vigor of tectonics in the Archean has important consequences for many aspects of the evolution of the Earth. Tectonic style directly influences (a) how and when continents formed

and why cratons remained stable and preserved over much of the Earth's history (Lenardic et al. 2003); (b) how tectonics-related events such as melting, remelting, and fluid-related alteration has changed the composition of the mantle from its primitive composition shortly after core formation to its modern composition (Shirey et al. 2008); and (c) the composition of the atmosphere and oceans through ► **degassing** (during volcanism) and regassing (at subduction zones) of volatiles and surface weathering (Lowe and Tice 2007; Rollinson 2007), and through that the emergence and evolution of life on Earth. Furthermore, if plate tectonics has been operative throughout the changing conditions of the Earth during its history, how does that relate to the viability of plate tectonics on the other terrestrial planets of our solar system, such as on Mars (which has no plate tectonics today, but might have had some during its earliest history) or Venus (which doesn't have plate tectonics, probably because of the lack of liquid water, but perhaps experiences episodic large-scale mantle overturns).

Future Directions

Integrated, four-dimensional lithospheric studies of Archean lithosphere are the key future research directions, particularly in poorly studied regions. Detailed geochronology within a well-established map framework continues to be key to understanding formation processes of ancient crust, particularly when coupled with ongoing reevaluation of uniformitarian assumptions given known aspects of secular change. Hf isotope determination of zircon can help discriminate juvenile crustal growth through subduction from volcanism and crustal recycling during episodes of plume magmatism. Further understanding of crustal growth processes will be aided by more complete knowledge on the origin of subcontinental lithospheric mantle: detailed studies of primary dunite-harzburgite xenoliths are required to determine the age, composition, and history of these more depleted rocks, and their properties tied into detailed regional seismic studies, including physical modeling of their geophysical response.

Additional work is also required on the ► **metamorphism** of granite-greenstone terranes, specifically precise dating of mineral assemblages related to magmatic and deformational events and P-T studies of granitic rocks as a counterpart to greenstones, to test models of cold greenstone diapirs in hot rising granites (partial convective overturn; Smithies et al. 2009). Additional studies are required on the origin of Archean calc-alkaline felsic volcanic rocks and high-Mg diorites to establish whether they are really the products of volcanic arc magmatism over an active subduction zone, as widely assumed, or the products of fractionation and crustal contamination of large tholeiitic magma chambers derived from mantle plumes. Additional research is required across the interval 3.3–2.9 Ga, in order to assess the tantalizing clues that there may have been a global change in crust-formation processes at this time, perhaps due to an increase in plate size and concomitant cooling of oceanic lithosphere and steepening of the angle of subducting oceanic lithosphere. Key open questions include the following: How did subduction initiate, and did plate tectonics remain operative from its first onset until today, or was it once more episodic (Sleep 2000)? Is the onset of plate tectonics related to any atmospheric and oceanic changes in the Archean, to the habitat that provided early life and its evolution, and to the presence of the Earth's magnetic field? How does Archean tectonics relate to the observed peaks in continental crust formation at 3.3, 2.7, 1.9, and 1.2 Ga (Condie 1998; Parman 2007)?

[Geology of Mars](#)

Definition

Areology (Greek, *Ares* “Mars” and *logos* “speech, science”) is the science of the planet ► [Mars](#), excluding its atmosphere. It comprises the study of the structure, composition, physical properties,

dynamics, origin, and evolution of Mars as well as the processes that formed and shaped Mars. The term areology is not frequently used because scientifically and methodologically it is synonymous to the term “Geology of Mars.” Thus it is common to use the latter term instead of “areology.”

Arginine

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Definition

Arginine, shown in Fig. 1, is one of the 20 ► [protein amino acids](#). Its molecular weight is 174.21. Its three-letter symbol is Arg and one-letter symbol is R. It has a guanidinium group ($\text{H}_2\text{NC}(=\text{NH})\text{NH}_2$) in its side chain. The side chain is basic with a pK_a of 12.48. When protonated, the positive charge of the guanidinium ion is delocalized on the three nitrogen atoms. The isoelectric point (pI) of arginine is 10.76, which is the highest among the protein amino acids. Adult humans are able to biosynthesize arginine, but infants cannot. Thus, it is an essential amino acid

Arginine,
Fig. 1 Structural formula
of arginine

only for infants. To date, arginine has not been found in extraterrestrial bodies like carbonaceous chondrites.

Argonium (ArH^+)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

ArH^+

Definition

Argonium is the argon hydride cation, ArH^+ . Argon has three naturally occurring isotopes, with the cosmically most abundant being ^{36}Ar , followed by ^{38}Ar , and then ^{40}Ar . On Earth, in contrast, ^{40}Ar is by far the most abundant isotope, derived primarily from the radioactive decay of ^{40}K . The K-Ar decay is important for geochronology. Argonium is the first noble gas molecule to have been found in space, with both the ^{36}Ar and the ^{38}Ar isotopologs observed by astronomers. Extensive laboratory studies of the rotational spectra and the electric

dipole moment have been carried out for both $^{36}\text{ArH}^+$ and $^{38}\text{ArH}^+$; ArH^+ is quite stable, with a dissociation energy of almost 4 eV.

History

Astronomically, argonium was first reported in the Crab Nebula, the remnant of the supernova observed by Chinese astronomers/astrologers in 1,054 CE (Barlow et al. 2013). The observed ^{36}Ar was presumably produced by ► [explosive nucleosynthesis](#) during the supernova event. Both $^{36}\text{ArH}^+$ and $^{38}\text{ArH}^+$ were more recently reported toward the Galactic Center molecular cloud SgrB2 (Schilke et al. 2014). Because ArH^+ reacts rapidly with molecular hydrogen, H_2 , but not at cold interstellar temperatures with atomic hydrogen, H, Schilke et al. suggest that ArH^+ may well be a useful tracer of the neutral atomic hydrogen in galaxies.

Atmospheric remote-sensing infrared exoplanet large-survey

Definition

Ariel, the atmospheric remote-sensing infrared exoplanet large-survey, is the fourth medium class mission within ESA's Cosmic Vision science program. Ariel is the first mission dedicated to studying the atmospheres of a statistically large and diverse sample of transiting exoplanets (≥ 500) through a combination of transit photometry and spectroscopy. The Ariel mission has been adopted in November 2020 and is due for launch in 2029 on board an Ariane 6.2 from Europe's Spaceport Kourou.

Overview

The Ariel mission aims to address the fundamental questions on what exoplanets are made of and how planetary systems form and evolve by investigating the atmospheres of many hundreds of diverse planets orbiting different types of stars. This large and unbiased survey will contribute to answering the first of the four ambitious topics listed in the ESA's Cosmic Vision: "What are the conditions for planet formation and the emergence of life?". Thousands of exoplanets have now been discovered with a huge range of masses, sizes, and orbits: from rocky Earth-like planets to large gas giants grazing the surface of their host star. There is no known,

discernible pattern linking the presence, size, or orbital parameters of a planet to the nature of its parent star. It is not known to date, whether the chemistry of a planet's surface and atmosphere is linked to its formation environment, or whether the type of host star drives the physics and chemistry of the planet's birth and evolution. Ariel is expected to observe around a thousand transiting planets, including gas giants, Neptunes, super-Earths, and Earth-size planets around a range of host star types. This comprehensive approach will underpin statistical understanding generating robust conclusions which are simply not possible with smaller samples or patchy coverage of the relevant parameter space.

By characterizing exoplanet atmospheres, the Ariel mission will address three fundamental questions:

- *What are the physical processes shaping planetary atmospheres?*
- *What are exoplanets made of?*
- *How do planets and planetary systems form and evolve?*

Equipped with an off-axis Cassegrain telescope, 1.1 m $\times$ 0.73 m elliptical in size, Ariel will use transit spectroscopy in the 1.1–7.8 μ m spectral range and photometry in multiple narrow bands covering the optical and near-infrared (NIR). The focus will be on warm and hot planets to take advantage of their presumably well-mixed atmospheres which should show minimal condensation and sequestration of high-Z materials (materials with a high atomic number of protons in the nucleus) and thus have the potential to reveal their bulk elemental composition, especially C, O, N, S, Si). Observations of the upper atmospheres of these warm/hot exoplanets will drive understanding of the early stages of planetary and atmospheric formation during the nebular phase and the following few million years. Ariel will significantly improve the picture of the chemical nature of the exoplanets and relate this directly to the planetary parameters and the type and chemical environment of the host star.

For this ambitious scientific program, Ariel is designed as a dedicated survey mission for transit and eclipse spectroscopy, capable of observing a large and well-defined planet sample within its 4-year mission lifetime. Transit, eclipse, and phase-curve spectroscopy methods allow us to measure atmospheric signals from the planet at levels of 10–50 parts per million (ppm) relative to the star. Given the brightness of the target host stars more sophisticated techniques, such as eclipse mapping, will also be used to give deeper insights. These observations require a specifically designed, stable payload and satellite platform with broad, instantaneous wavelength coverage to detect many molecular species, probe the thermal structure, identify clouds, and monitor the stellar activity. The wavelength range covered by Ariel includes all the expected major atmospheric gases from, for example, H_2O , CO_2 , CH_4 , NH_3 , HCN , H_2S through to the more exotic metallic compounds, such as TiO , VO , and condensed species.

With the exquisite, multi-band, high-speed sampling of Ariel's Core Survey data also a variety of science can be executed in addition to the core scientific objectives of Ariel. It will be possible to gain new insights into stellar variability across the Hertzsprung-Russell Diagram, on phenomena related to stellar activity and stellar flares, exomoons, exorings, exocomets, and exotrojans or on dust clouds in catastrophically disintegrating exoplanets (CDEs), just to name a few.

Humans have been speculating about the cosmos and the possible existence of other worlds throughout recorded history, and probably for longer. Since the discovery of exoplanets in the 1990s this field of astronomy and planetary science has exploded, being one of the most exciting and dynamic. Currently we know over 4300 exoplanets orbiting in excess of 3000 host stars. We know the sizes of about three-fourths of these, and for about one-fifth we have mass information. Only for a few percent of all known exoplanets do we have both, enabling rudimentary conclusions about their bulk compositions, and comparison with models of planetary structure, and for even fewer do we have atmospheric information. We now stand at

Ariel Space Mission, Fig. 1

the threshold of a revolution in our understanding of our place in the Universe: Ariel is the next step. Only by performing a chemical census of a large, diverse sample of about a thousand exoplanets, studying each as a world in its own right, and as a member of a (sub-)population, can we hope to understand how our own Solar System, and our own planet Earth, fit in the big picture of innumerable other worlds. We are the first generation to know that the ancient hypothesis about planets around other stars is true. We are also the first to be capable of studying these worlds. Ariel will seize this unique opportunity and enable transformative science in this exciting field (Fig. 1).

of Technology, Atlanta, GA, USA

Definition

An aromatic hydrocarbon is a cyclic hydrocarbon where the series of saturated and unsaturated carbon-carbon bonds satisfies Hückel's rules, that is, where the number of electrons in double and triple bonds in the ring is $4n + 2$, where $n = 0$ or any positive integer. The name derives from the fact that the first such molecules discovered tended to have an aromatic odor. They are typically somewhat more stable than their hydrogen-saturated analogues. Aromatic hydrocarbons may be monocyclic or polycyclic.

Arrhenius Plot

Jeffrey Bada

Scripps Institution of Oceanography, La Jolla,
CA, USA

Definition

In 1889, the Swedish chemist Svante Arrhenius showed that the rate of a chemical reaction as a function of temperature could be described by the equation

$$\ln k = \ln A - E_a/RT$$

where k is the reaction rate, R is the universal gas constant, E_a is the ► [activation energy](#) (the energy required in order for the reactants to react), T is the absolute temperature (in degrees K), and A is the so-called pre-exponential factor (associated with collision and transition state theory).

A plot of $\ln k$ versus $1/T$ often yields a straight line, the slope of which is equal to the activation energy of the reaction divided by the universal gas constant (E_a/R) and the y-intercept of which is equal to $\ln A$.

History

Svante August Arrhenius (1859–1927), Swedish scientist, received the Nobel Prize in Chemistry in 1903 “in recognition of the extraordinary services he has rendered to the advancement of chemistry by

his electrolytic theory of dissociation.” Among other achievements, Arrhenius is famous for the Arrhenius equation, which gives the dependence of the rate constant k of a chemical reaction on the temperature T (in K) and the activation energy of the reaction. For astrobiologists, Arrhenius is famous for his thoughts that microscopic forms of life, for example, ► [spores](#), can be propagated in space, driven by the radiation pressure from the Sun and thereby seeding life from one planet to another or even between planets of different stellar systems. Arrhenius based his considerations on the fact that the space between the planets of our Solar System is teeming with micron-sized cosmic dust particles, which at a critical size below $1.5\ \mu\text{m}$ would be blown away from the Sun with high speed pushed by radiation pressure of the Sun. Herewith Arrhenius provided a scientific rationale for the theory of ► [Panspermia](#), now called Radiopanspermia.

Trans-Neptunian object · Complex organics · Protoplanetary disk

Definition

Arrokoth is a trans-Neptunian object located in the Kuiper belt. It became the farthest and most primitive object in the Solar System ever visited by a spacecraft when the New Horizons space probe conducted a flyby on 1 January 2019. It was previously named 2014 MU69, then Ultima Thule, and finally Arrokoth. The name Arrokoth means “sky,” in the Powhatan language, and was chosen to represent the Native American living in Maryland, where both New Horizons and the Hubble Space Telescope (which discovered Arrokoth in 2014) are operated.

Discovery

Arrokoth was discovered on 26 June 2014 by the New Horizons team, using the Hubble Space Telescope, as part of a search for a Kuiper belt object reachable by New Horizons after the Pluto flyby in 2015.

Orbit and Classification

Arrokoth orbits the Sun at an average distance of 44.6 astronomical units (AU), taking 297.7 years to complete a full orbit. Arrokoth's orbit is nearly circular (with an eccentricity of only 0.042), with a perihelion at 42.7 AU and an aphelion at 46.4 AU. Its orbital inclination is 2.45° . Arrokoth is classified as a member of the cold classical Kuiper belt (referring to its quasi-circular, near-ecliptic orbit), which represents a relic of the primordial Kuiper Belt.

Shape

Arrokoth's bilobate shape was initially established from stellar occultations in 2017 and 2018, and refined by the New Horizons flyby. Arrokoth is a contact binary 36 km long, consisting of two planetesimals connected by a narrow and bright neck. The two lobes were likely once two objects that merged in a slow collision. The larger lobe ($21 \times 20 \times 9$ km) is relatively

flattened and moderately elongated, whereas the smaller lobe ($15 \times 14 \times 10$ km) is less flattened. The cause of Arrokoth's unexpected flatness is uncertain, with various explanations involving sublimation or centrifugal forces. The longest axes of the two lobes are nearly aligned, suggesting that the lobes were mutually locked, likely due to tidal forces, before merging. From geomorphological analysis, the larger lobe appears to be an aggregate of 8 or so smaller units, each approximately 5 km across.

Mass and Density

In the lack of moons (with upper limits at the 100–180 m diameter out to 8000 km from Arrokoth), the mass and therefore density of Arrokoth remain unknown, though the bulk density is estimated to be very low, similar to that of comets (~ 0.6 g/cm³). A strict upper limit to the density is 1 g/cm³, otherwise the neck would be excessively compressed by the mutual gravity of the two lobes and the entire object would gravitationally collapse into a spheroid.

Rotation and Temperature

Arrokoth's rotation period is 15.938 hours. Its rotational axis is tilted 99° to its orbit. Consequently, as it orbits around the Sun, one pole of Arrokoth faces the Sun continuously while the other pole faces away.

The average surface temperature of Arrokoth at the time of New Horizons encounter is estimated to be around 42 K, with a maximum of around 60 K on the illuminated subsolar point. The mean brightness temperature on the winter night side was measured to be 29 ± 5 K, which implies thermal radiation from the subsurface.

Surface Composition and Appearance

Color and Composition

Preliminary HST observations in 2016 revealed that Arrokoth has a red coloration, similar to the

“ultra red” population of cold classical Kuiper belt objects. The red coloration is attributed to the presence of complex organic compounds, produced from the photolysis of various simple surface compounds by cosmic rays and ultraviolet solar radiation.

Spectral measurements from New Horizons revealed the single signature of methanol ice (noteworthy, water ice was not spectrally identified), a component that was also identified in a handful of other Centaurs/Trans-Neptunian objects, and Arrokoth spectra can be fit with mixtures of methanol with red and neutral materials.

In general, both lobes share the same properties in albedo, color, and composition. The mean 0.6 μ m reflectance of Arrokoth is 0.24 (similar for both lobes). However, at the resolution of the available imagery, the normal reflectance varies across the surface from 0.18 to 0.35 due to various discrete geological units and bright features.

Geology

Arrokoth has a smooth surface, with a general paucity of craters (about ten craters only were detected, and except for one, they are all smaller than 1 km). Craters' densities are smaller than those of most other small bodies. This suggests an ancient surface age (about 4 billion years), a dearth of Kuiper Belt objects <1 km, and a benign collisional environment, associated with the slow orbital speeds of Kuiper belt objects that could potentially have impacted Arrokoth (300 m/s).

Internal Structure

Arrokoth's interior is likely composed of mostly amorphous water ice and rocky material. Trace amounts of gaseous methane and other volatiles may also be present in the interior, trapped in water ice. Assuming that Arrokoth has an internal heat source caused by the radioactive decay of radionuclides and a comet-like porosity, trapped volatile gases would migrate outward and escape from the surface. The escaped gases may subsequently freeze and deposit on the surface.

Formation

As a classical cold Kuiper Belt object, Arrokoth likely formed near its current location and stayed there for the entire Solar System 4.6 Gyr age. As such, it has always been in a cold, weak-radiation environment. The flattened, weakly cratered, and aligned lobes indicate that Arrokoth never experienced a catastrophic collision. Instead, it was likely formed from a gentle (~m/s) collision from two objects born in the same local cloud of bodies, after tidal evolution of a close, co-orbiting binary. This hypothesis gives strong support to pebble cloud gravitational collapse models based on streaming or other instabilities, in which icy pebbles are slowed down due to gas-dust drag. The scenario is further supported by the lack of strong color or composition heterogeneity between the two lobes, as expected to result from the merging of two bodies from the same local cloud. The presence of topography geomorphological units on the larger object indicates that it had likely formed from the coalescence of smaller planetesimals prior to merging with the other object.

Definition

Artificial Cell Division is one of the most crucial tasks to be performed by an Artificial Cell in order to be considered alive or life-like. Besides self-assembly, self-organization, morphogenesis by energy dissipation, and the ability of self-sustenance by metabolism, self-replication is one of the necessary requirements for a chemical system to become biological. This usually consists of the two steps, division and regrowth. Division can be symmetric, that is, into equally sized daughters, or asymmetric, although every daughter needs to inherit sufficient resources to be able to regrow autonomously. Division is often considered to be – but is not necessarily – binary. In order to distinguish autonomous division from spontaneous fission induced by internal or external mechanical destabilization of the compartment, it needs to be coupled to energy dissipation within

the artificial cell. In biological systems, cell division is always coupled to information replication and indispensable for the maintenance and evolution of an organism.

History

In the most predominant perception today, artificial cells or protocells are composed of phospholipid or fatty acid membranes that enclose an aqueous compartment, resulting in small to giant vesicles (several 10 nm to several 10 μ m). There are many experimental approaches how to initiate and facilitate the division of such vesicles. Most importantly, the process itself requires sufficiently high forces to drive the mechanical transformation of the vesicle compartment, in particular to overcome surface tension. These forces can be brought about by surface-to-volume growth, for example, through the incorporation of fatty acids or lipids (Zhu and Szostak 2009; Castro et al. 2019), osmotic stress due to enzymatic reactions within (Miele et al. 2020), destabilization of the surface by active membrane-curvature induction (Litschel et al. 2018) or force-inducing elements within, such as active polymers (Kretschmer et al. 2019). Besides these membrane-enclosed artificial cells, it has previously been suggested that cell-like compartments could have formed and acquired functions of life without a membrane boundary (Oparin 1938). Coacervation or liquid-liquid phase separation may have been sufficient to confine reactions with the required properties of self-catalysis and metabolic self-sustenance by energy dissipation which may under certain conditions lead to autonomous growth and division (Zwicker et al. 2017). However, the lack of a selective boundary does not likely support such a system to emerge new functionality, nor protect informational identity as required for Darwinian evolution.

Reaction network

Definition

Artificial chemistry (AC) is a field of research that studies systems that are similar to, and commonly a generalization of, chemical networks. Those studies are usually done through computer simulations which are also called artificial chemistries. An AC can be defined as triplet $\{M, R, A\}$, with M being the set of possible molecules (sometimes infinite), R the set of possible reactions, and A the algorithm (Dittrich et al. 2001).

Overview

Artificial chemistry grew as a field from the early 1990s. Different aims converged in producing this field.

One of the aims of artificial chemistry was to investigate evolution and the appearance of life. Some of the main questions that have been investigated deal with biology, proto-biology, and evolution and take a bottom-up approach to ► [artificial life](#):

- Can we generate an artificial chemistry that can generate an artificial life?
- What kind of chemistry can sustain life?
- How does the Darwinian evolutionary process depend upon the chemistry on which it is based?

Of course, as we extrapolate out of chemistry the basic network of relations that can produce life, this would eventually help to recognize life in different contexts.

Another, more general, aim was to study reaction networks. Reaction networks appear in multiple fields, but our ability to study them has generally been limited by a difficulty in solving differential equations where the number of different interacting elements (*diversity*, i.e., number of equations) were too high, and the quantity of each participating element in the reaction network (*population size*) was too low (which could lead to an element disappearing and the set of reactions changing). Some artificial chemistries investigated exactly this problem. As such the aim of

artificial chemistries has often been a qualitative study, looking for *what* sets of molecules would be present in the reactor, more than *how many* elements would be present for each type of element in the system (Fontana and Buss 1996).

Due to the computational difficulty in simulating a chemical system that is both unbounded in the complexity of the molecules involved and that permits a faithful representation of space, the field tends to be divided into two main subfields: Complex Artificial Chemistries and Spatial Artificial Chemistries.

Complex Artificial Chemistries are the most simple type of system and assume a well-mixed reactor. Each molecule is either present or absent, with no information about the position. Pairs of molecules are then randomly selected and reacted. Such a simple algorithm frees the computational resources permitting the presence of complex molecules, with different behaviors. It is not uncommon for artificial chemistries to study the behavior of little program strings with computational capabilities (traditionally lambda terms).

Spatial Artificial Chemistries traditionally study systems made up of many simple elements, floating in a 2D or in a 3D spatial environment. The basic elements (in some systems called *atoms*) can often link together creating long chains (usually called *molecules*). In the first pioneering works of Spatial Artificial Chemistries, the positions of the molecules were imprecise, as each molecule was generally assigned to a position on a lattice. Recent computational progress permitted a more faithful representation of the movement using differential equations (Fellermann 2009).

Basic Methodology

The methodology is slightly different for Spatial Artificial Chemistries and for Complex Artificial Chemistries.

Complex Artificial Chemistries, as mentioned before, are essentially reaction networks with a high diversity and a low population size. Such an AC can be defined as a triplet {molecules, reactions, algorithm}. Reactions are usually binary

(i.e., two molecules reacting and generating a third). Yet not all pair of molecules can react. When two molecules cannot react, they are said to be *elastic*. The basic algorithm is generally very simple:

1. Define a Soup S as a multiset of m molecules out of M .
2. Two molecules are randomly selected.
3. If the two molecules can react, a reaction takes place:
 1. The result of the reaction is inserted in the Soup.
 2. A random molecule is extracted from the Soup and eliminated.
4. Go to 2.

In many Artificial Chemistries, the reactions are catalytic, so when two molecules react, they are *not* taken away from the Soup while their product is added to the Soup (3a). Instead, the molecules catalytically induce the formation of the new molecule out of a substrate of basic material (too vast and ubiquitous to be explicitly modeled), while the disappearance (3b) would model the outflux due to molecules being washed away or breaking apart (Dittrich et al. 2001). This traditional structure has been strongly criticized (e.g., for not considering conservation of mass), and many alternatives have been offered but generally with only partial differences in the observed behavior. Traditionally the standard way to investigate such a system is to run it until no new molecule would be generated, at which point the resulting multiset is studied. Lately, a more advanced method has been to calculate all the possible sets where the system could stop (called organizations) and study the structure of the lattice of organizations and use this to map the movement of the artificial chemistry as time progresses (Kaleta 2009).

Spatial Artificial Chemistries start in general with a set of atoms, to which a position in space is randomly assigned. At each time step all the atoms are randomly moved, and when two atoms end up near each other, they have the possibility of colliding. Unless the system is superimposed on a lattice, the movement of the molecules would

follow a Brownian motion style of movement or a dissipative particle dynamic style, where the forces interacting on a molecule are taken into account in greater detail (Fellermann 2009).

Key Research Findings

The first result in AC is that there are sets of molecules, called *organizations*, which are qualitatively stable, in the sense that each molecule present in the set can be generated by the reactions inside the set and that all reactions inside the cell can only generate molecules that are already inside the cell. Such organizations form an algebraic lattice, and in the absence of external inputs, each experiment eventually leads to the system reaching one of those sets. As artificial chemistries can be represented using ordinary differential equations (ODE), it has been shown that fixed points in the ODE of the system exist only inside organizations. In other words, if we take a fixed point of the system, find the molecules that are present with a quantity higher than 0, and then this set of molecules forms an organization. Those results permit a preliminary study of an artificial chemistry by finding (through algebraic studies) the lattice of organizations and produce a map of the system on which it is possible to track the changes in the system (Dittrich and Speroni di Fenizio 2007).

Spatial Artificial Chemistries have been successfully used to model the lipid bilayer of cell membranes and to investigate the spontaneous emergence of artificial life protocells. More recently, experiments have been carried out generating protocells that are able to reproduce (Rasmussen et al. 2007).

Applications

While the long-term aim of artificial chemistry, to investigate the appearance of life, has not been reached, a number of partial findings were recognized as being useful in different fields. As Complex Artificial Chemistry can investigate reaction network with a high diversity, they are often the

right tool to study ► [biological networks](#). In particular, studies have been done on gene regulatory networks and the internal metabolism of a cell. In this regard, AC has started merging with the other tools inside systems biology and bioinformatics. Other studies have tried to consider social systems, language, and economical systems (Dittrich et al. [2001](#)).

Future Directions

Spatial Artificial Chemistries and Complex Artificial Chemistries are going in separate ways, mostly answering different questions about nature. Spatial Artificial Chemistries try to produce a minimal cell, but have not yet succeeded in generating a spontaneous emergence of a full Darwinian evolutionary system. So we can expect more research to go in this direction. Results in Complex Artificial Chemistries have been more connected with systems biology, and artificial chemistries have been used to explicitly study system biology models, and recent studies show that it is possible to use AC to build programmable systems made up of many interacting components. In the future, we can expect those two trends to merge, as scientists investigate chemistries that can evolve and that can be programmed to evolve.

Definition

Artificial ► [life](#) uses software simulation and, to a lesser degree, robotics in order to abstract and elucidate the fundamental mechanisms common to living organisms. It focuses on the rule-based mechanisms making life possible, supposedly neutral with respect to their underlying material embodiment, and to replicate them in a non-biochemical substrate. In artificial life, the

importance of the substrate is purposefully understated for the benefit of the function. Minimal life begins at the intersection of a series of processes that need to be isolated, differentiated, and duplicated as such in computers. Only software development and running make it possible to understand the way these processes are intimately interconnected in order for life to appear at the crossroads.

Overview

Artificial life obviously relates to astrobiology; this other recent interdisciplinary field of scientific research equally centered on life and the study of its origins, not only on the obvious environment of Earth but also throughout the universe. Astrobiology cannot restrict itself to a mere materialistic view of life, in order to detect it elsewhere, as the material substrate could be something totally different. This substrate could be as much singular on a distant planet as it could be in the RAM memory somewhere in a university computer laboratory. The presence of life might be suspected through its functions, much before scientists are able to dissect it. Artificial life does not attempt to provide an extra thousandth attempt at the definition of life, any more than do most biologists. As a matter of fact, the concept of “life,” as opposed to “gravity” or “electromagnetism” or “quantum reduction of a wave packet,” has already been in widespread existence prior to any scientific reading or reification. The rejection of an authoritative definition of “life” is often compensated for by a list of functional properties that never finds unanimity among its authors. Some demand more properties, and others require fewer of those properties that are often expressed in terms of a vague expression such as “self-maintenance,” “self-organization,” “metabolism,” “autonomy,” ▶ “self-replication,” and “open-ended evolution.” A first determining role of artificial life consists in the writing and implementing of software versions of these properties and of the way they do connect, so as to render them unambiguous, making them algorithmically precise enough that, at the end, the only reason for disagreement on the

definition of life would lie in the length or the composition of this list and on none of its items.

The biologist obviously remains the most important partner; but what may he expect from this “artificial life”? These computer platforms could be useful in several ways, presented in the following in terms of their increasing importance or by force of impact. First of all, they can open the door to a new style of teaching and advocating of the major biological ideas, that is, computer software as pedagogical help, as, for example, Richard Dawkins (1986) who, bearing the Darwinian good news, did so with the help of a computer simulation where sophisticated creatures known as “biomorphs” evolve on a computer screen by means of a genetic algorithm. These same platforms and simulations can, insofar as they are sufficiently flexible, quantifiable, and universal, be used more precisely by the biologist, who will find in them a simplified means of simulating and validating a given biological system under study. Cellular automata, Boolean networks, genetic algorithms, and algorithmic chemistry are excellent examples of software to download, parameterize, and use to produce the natural phenomena required. Their predictive power varies from very qualitative (their results apparently reproduce very general trends of the real world) to very quantitative (the numbers produced by the computer may be precise enough to be compared with those measured in the real world). Although being at first very qualitative, a precise and clear coding is already the guarantee of an advanced understanding accepted by all. Algorithmic writing is an essential stage in formalizing the elements of the model and making them objective. The more the model allows us to integrate what we know about the reality being reproduced, that is, the detailed structures of objects and relationships between them, the more the predictions will move from qualitative to precise and the easier the model will be to validate according to the Karl Popper ideal falsifying process.

Finally, through systematic software experiments, these platforms can lead to the discovery of new natural laws, whose impact will be greater if the simulated abstractions will be present in

many biological realms. In the 1950s, when Alan Turing (1952) discovered that a simple diffusion phenomenon propagating itself at different speeds, depending on whether it is subject to a negative or positive influence, produces zebra or alternating motifs, it had a considerable effect on a whole section of biology studying the genesis of forms (animal skins, shells of sea creatures (Meinhardt 1998)). When some scientists discovered that the number of attractors in a Boolean network or a neural network exhibits a linear dependency on the number of units in these networks (Kauffman 1993, 1995), these results are equally well applied to the number of cells expressed as dynamic attractors in a genetic network or the quantity of information capable of being memorized in a neural network. Entire chapters of biology dedicated to networks (neural, genetic, protein, immune, hormonal) had to be rewritten in the light of these discoveries. When some scientists recently observed a non-uniform connectivity in many networks, whether social, technological, or biological, showing a small number of key nodes with a large number of connections and a greater number of nodes with far fewer, and when, in addition, they explained the way in which these networks are built in time (Barabasi 2002) by preferential attachment, again biology was clearly affected. Artificial life is of course at its apogee when it reveals new biological facts, destabilizing the presuppositions of biologists or generating new knowledge, rather than simply illustrating or refining the old.

In the next section, I shall attempt to set out the history of life as the disciples of artificial life understand it, by placing the different landmark steps on a temporal and causal axis, showing which one is indispensable to the appearance of the next and how it connects to the next. This history will certainly be very incomplete and full of numerous unknowns, but most people involved in artificial life will be in agreement. They will mainly disagree on the number of these functions and on the causal sequence of their appearance, acknowledging, however, that the appearance of any would have been conditioned by the presence and the functioning of the previous ones. The task of artificial life is to set up experimental software

platforms where these different lessons, whether taken in isolation or together, are tested, simulated, and, more systematically, analyzed. I shall sketch some of these existing software platforms whose running delivers interesting take-home messages to open-minded biologists.

The History of Life as Seen by Artificial Life Proponents

Appearance of Chemical Reaction Cycles and Autocatalytic Networks

In order for a system to emerge and maintain itself inside a soup of molecules that are potentially reactive and contain very varied constituents (which could correspond to the initial conditions required for life to appear, i.e., in the primordial soup), this reactive system must form an internally cycled network or a closed organization, in which every molecule is consumed and reproduced by the network. Above all, in order for life to begin, all of the constituent components must have been able to stabilize themselves in time. These closed networks of chemical reactions are thus perfect examples of systems, which, although heterogeneous, are capable of maintaining themselves indefinitely, despite the shocks and impacts that attempt to destabilize them. This comes about through a subtle self-regeneration mechanism, where the molecules end up producing those molecules that have produced them. It may be obtained on a basic level in a perfectly reversible chemical reaction but can be obtained more subtly in the presence of a lot of intermediary molecules and catalysts. By this reaction-based roundabout in which they all participate, all molecules contribute to maintaining themselves at a constant concentration, compensating and reestablishing any disruption in concentration undergone by anyone of them. The bigger the network, the more stable it should be and the more molecules it will maintain in a concentration zone that will vary very little, despite external disruptions.

A network of this kind will be materially closed but energetically open if none of the molecules appears in or disappears from the network as a result of material fluxes, whereas energy,

originating in external sources, is necessary for the reactions to start and take place. The presence of such an energy flux, maintaining the network far from the thermodynamic equilibrium, is needed, since, without it, no reactive flow would be possible circulating through the entire network. A molecular end of the cycle must be reenergized in order to start again the whole circular reaction process. This cycle thus acts as a chemical machine, energetically driven from the outside. As soon as one of the molecules is being produced in the network without, in its turn, producing one of the molecules making up the network, it absorbs and thus destroys the network. In the presence of molecules of this kind, produced but nonproductive (a kind of waste), the only way of maintaining the network becomes to feed it materially and to make it open to material influx. The network acts on the flow of material and energy as an intermediate ongoing stabilization zone, made up of molecules that may be useful to other vital functions (such as the composition of enclosing membranes or catalyzing self-replication), to be described in the following sections. It transforms, as much as it “keeps on,” all the chemical agents that it recruits. Biologists generally agree that a reactive network must exist prior to the appearance of life, at least to catalyze and make possible the other life processes such as genetic reading and coding; it is open to external influences in terms of matter and energy but necessarily contains a series of active cycles. They are most often designated as ► “metabolism” or “proto-metabolism,” the most popular and active advocates of this “metabolism-first” hypothetical scenario of the origin of life being (De Duve 2002; Ganti 2003; Maynard Smith and Szathmary 1999; Kauffman 1993; Shapiro 2007; Dyson 1999).

Lenaerts and Bersini (2009) give priority to the study of chemical reaction networks, viewing them as key protagonists in the appearance of life. These chemical reaction networks, where the nodes are the molecules participating in the reactions and the connections are the reactions linking the reacting molecules to the molecules produced, are generally characterized by fixed point dynamics, the chemical balances during which the producers and the products mutually

support each other. The attractors in which these networks fix themselves are as dynamic (the concentrations slowly stabilize) as they are structural (the molecules participating in the network are chosen and “trapped” by the network as a whole). These networks are perfect examples of systems that combine dynamics (the chemical kinetics in this case) and metadynamics (the network topological change), as new molecules may appear as the results of reactions while some of the molecules in the network may disappear if their concentration vanishes in time. Both the structure of the network and the concentration of its constituents tend to stabilize over time. Kauffman (1993, 1995) and Fontana (1992) were the forerunners in the study of the genesis and properties of these networks. Figure 1 illustrates the work of these two artificial life pioneers, dedicated to the study of prebiotic chemistry, limiting the reactions studied to polymerization, such as $aa + bb \rightarrow aabb$, or, inversely, depolymerization or hydrolysis, such as $abaa \rightarrow ab + aa$.

Kauffman showed that provided the probability that a reaction takes place is affected by the presence of a catalyst, which is itself produced by the network (in such a case the whole network is said to be autocatalytic), a phenomenon of percolation or phase transition, characteristic of this type of simulation, is produced. For probabilities that are too low, the network does not pop up because the reactions are too improbable, but as soon as a threshold value is reached for this same probability, the network “percolates,” giving rise to multiple molecules produced by multiple reactions. Kauffman grants a privileged status to this threshold value and to the giant “explosive” network resulting from it (in his scenario of the origin of life), without really arguing the reason why such a status should exist, but passing the immense interest and enthusiasm that the phenomena of phase transitions arouse among physicists onto the world of biology. Fontana for his part is concerned with the inevitable appearance of reaction cycles (such as that illustrated in Fig. 1). All the molecules produced by these cycles in the network in turn produce molecules of the network. He is among those many biologists who see these closed networks or

Artificial Life,

Fig. 1 Representation of a network of chemical reactions of polymerization ($a + b \rightarrow ab$) and depolymerization ($ab \rightarrow a + b$) taking place in a simulated chemical reactor. Molecules are represented by *circles* and reactions by *squares*. Each reaction can be catalyzed, like the *arrows* pointing to the *squares* show, by a molecule of the network (giving rise to an autocatalytic network). Some molecules can appear (like the molecule “aab”) or simply disappear from the network. Reaction cycles can appear, like the one surrounded in the figure ($aa \rightarrow baaaa \rightarrow baaaaaab \rightarrow baaa \rightarrow aa$)

organizations as forming a key stage in the appearance of life, due both to their stability and to the fact that they form structural and dynamic attractors for the system. They cause a stabilization and internal regulation zone together with an energetic motor in a chemical soup, which is continually being crossed by a flow of matter and energy. Fontana goes on to show how these networks are also capable of self-regeneration and self-replication.

Lenaerts and Bersini (2009) have programmed the genesis of these chemical reaction networks by adopting the object-oriented (OO) programming paradigm. The OO simulator aims to reproduce a chemical reactor and the reaction network that emerges from it (like that shown in Fig. 2). This coevolutionary (dynamics + metadynamics) model incorporates the logical structure of constitutional chemistry and its kinetics on the one hand and the topological evolution of the chemical reaction network on the other hand. The network topology

influences the kinetics and the other way round, since only molecules with a sufficient concentration are allowed to participate in new reactions (to avoid a combinatorial explosion of molecules and reactions). The model is expressed in a syntax that remains as close as possible to real chemistry. Starting with some initial molecular objects and some initial reaction objects, the simulator follows the appearance of new molecules and the reactions in which they participate, as well as the development of their concentration over a period of time. The molecules are coded as canonical graphs. They are made up of atoms and bonds that open, close, or break during the reactions. The result of the simulation consists in various reaction networks, unfolding in time and whose properties can be further studied (for instance, the presence and the properties of reaction cycles or the nature of the network-particular topology such as scale-free or random).

One of these reaction schemes, in addition to just cycling, can also be autocatalytic, when a

Artificial Life, Fig. 2 The OO chemical simulator developed by Lenaerts and Bersini (2009). On the *left*, the molecules are represented as canonical graphs. On the

right, the outcome of the simulator is an evolving reaction network, which can be studied in its own right (the presence of cycles, the type of topology)

product of the reaction cycle has twice the concentration of one of the reactant: $a + b \rightarrow a + a$. This is, for instance, the case of the so-called formose reaction (that Ganti and Szatmary have discussed at large in Ganti 2003), during which a two-carbon molecule, reacting twice with a monomer composed of one carbon, leads to a four-carbon molecule, which then splits in order to duplicate the original molecule. This is the chemical variant of genetic self-replication, since in both cases an original molecule is duplicated. As will be discussed later, Ganti has been the first to connect and synchronize these two replication processes, chemical and genetic, in order for the cell to simultaneously duplicate its boundary, its metabolism, and its informational support. In the presence of autocatalysis, the reaction kinetics amounts to an exponential increase and, more interestingly, when various autocatalytic cycles enter in antagonistic interaction, turns out to be responsible for symmetry breaking (one of the cycle, initially favored, wins and takes it all). The early origin of life should not be studied without taking account of the self-organization of chemical networks, the emergence and antagonism of autocatalytic cycles, and how energy flows drive the whole process. Such

chemical networks are, for instance, appealing to the effort to understand the onset of biological homochirality as the destabilization of the racemic state resulting from the competition between enantiomers and from amplification processes concerning both autocatalytic competitors (one left oriented and the other right; see Plasson et al. 2007). The chemical reaction network under study (shown in Fig. 3) is made up of the same type of polymerization and depolymerization reactions as the one studied by Fontana. In the additional presence of epimerization reactions allowing the transformation of a right-hand monomer into a left-hand one and vice versa, the concentration of one family of monomers (for instance, the left one) vanishes in favor of the other. The flux of energy is transferred and efficiently distributed through the system, leading to cycle competitions and to the stabilization of asymmetric states.

Production by This Network of a Membrane Promoting Individualization and Catalyzing Constitutive Reactions

The appearance of a reaction network of this kind undeniably creates the stability necessary for exploiting its constituents in many reactive

Artificial Life, Fig. 3 The prebiotic chemical reactor system responsible for a homochiral steady state studied by Plasson et al. (2007). The complete set of reactions is indicated, containing activation (the necessary energy source), polymerization and hydrolysis (which together shape the cycles), and epimerization (which induces the competition between the enantiomers)

systems such as the ones dedicated to the construction of ► [membranes](#) or the replication of molecules carrying the ► [genetic code](#). This network also acts as a primary filter as it can accept new molecules within it but can equally well reject other molecules seeking to be incorporated within it. They will be rejected, as they do not participate in any of the reactions making up the network. Can we see a primary form of individualization in this network? No, because by definition, it can only be unique as no spatial frontier allows it to be distinguished from another

network. Although it is roughly possible to conceive of an interpenetration of several chemical networks, establishing a clear separation between these networks would remain a problem.

It would seem fundamental that a living organism of any kind can be differentiated from another. We know that the reproduction of a second organism from a first is a central mechanism of life and can only operate if the “clone” elaborates something to spatially distinguish itself from its “original.” The best way of successfully completing this individualization and to be able to distinguish between these networks is to revert to a spatial divide, which can only be produced by some form of container capable of circumscribing these networks in a given space. Biochemists are well acquainted with an ideal type of molecule, the raw material for these membranes in the form of lipid/amphiphilic molecules or fatty acids, the two extremities of which behave in an antagonistic fashion – the first hydrophilic, attracted to water, and the second hydrophobic, repulsed by it. Quite naturally, these molecules tend to assemble in a double layer (placing the two opposing extremities opposite to each other), formed by the molecules lining up and finally adopting the form of a sphere to protect the hydrophobic extremities from water. Like soap bubbles, these lipid spheres are semipermeable and imprison the many chemical components trapped during its formation. They do, however, actively channel in and out the most appropriate chemicals for maintaining themselves.

In assimilating living organisms to autopoietic systems, Varela et al. (1974) were the first to insist that this membrane should be endogenously produced by the elements and the reactions making up the network (e.g., lipids would come from the reactions of the network itself) and would in return promote the emergence and self-maintenance of the network. The membrane can help with the appearance of the reactive and growing network by the frontiers that it sets up, by the concentration of certain molecules trapped in it, or by acting as a catalyst to some of the reactions due to its geometry or its makeup. Basically, autopoiesis requires a cogeneration of the membrane and of the reactive network that it “walls up.” The

Artificial Life, Fig. 4 Simulation by means of cellular automata of the autopoietic model originally proposed by Varela. The minimal cell can easily be seen, together with the catalysts and the substrates that it encapsulates

network presents a double closure – one chemical, linked to the cycling chain of its reactions, and another physical, due to the frontiers produced by the membrane. In the cellular automata model of Varela (Varela et al. 1974; McMullin and Varela 1994) illustrated in Fig. 4, there are three types of particles capable of moving around a two-dimensional surface: “substrates,” “catalysts,” and “links.” The working and updating rules of these cellular automata go as follows:

- If two substrates are near a catalyst, they disappear to create one single link where one of the two was located.
- If two links are near each other, they link up and attach themselves to each other. Once attached, these links become immobile.
- Each link is only allowed to attach itself to two other links at the most. This allows the links to form chains and to be able to make up a closed membrane.
- The substrates can diffuse through the links and their attachments, while the catalysts and the other links cannot. We can therefore understand how the process of the cogeneration comes about. The membranes shut in the catalysts and the links, which in turn support the membrane by being essential to its formation and regeneration.
- The reactions creating the links are reversible, as the links can recreate the two original substrates (and thus cause the membrane to deteriorate), but at a lower speed. When this happens, the attachment between the links also disappears.

Continuous updating and execution of these rules produces minimal versions of reactive systems, physically closed and confined by means of a membrane, which is itself produced by the reactive system. For Varela and the others following him, this turns out to be an essential stage in the road to life. Running the software, many difficulties are encountered such as the simple attainment of a closed cell on account of the many more possibilities for the membranes to unfold in a straight way. Only software simulations can interconnect the physical compartment played by the membrane with the generating metabolism and further show how far from obvious it is for these two systems to mutually sustain each other.

The whole, interactive “metabolism and membrane” prefigures a minimal elementary ► **cell**, which already seems capable both of maintaining itself and detaching itself from its environment and from cells similar to it. It is at this stage on the way to establishing a better and more exact characterization of life that the definition given by Luigi Luisi (2002) takes on its full meaning (restating the idea of autopoiesis in more biological terms). “Life is a system which can be self-maintaining by using external energy and nutritional sources to the production of its internal constituents. This system is spatially circumscribed by a semipermeable membrane of its composition.” In the footsteps of Varela, considering life impossible without a way for individualization and compartmentalization, the constitution of the membrane by simple self-organization or self-assembly processes of bipolar molecules (hydrophilic and hydrophobic) has become a very popular field of artificial life. It is indeed rather simple to reproduce this

Artificial Life, Fig. 5 Simulation of a minimal cell based on A-B (A is hydrophobic and B hydrophilic) and water molecules. All molecules move in reaction to repulsive forces of different intensities and thermal agitations. The *pink dots* are the A; the *gray dots* are the B that do connect to give A-B (represented in *red and black*) by a simple chemical reaction. The *blue dots* are the water molecules

phenomenon in software (as illustrated in Fig. 5). You need water molecules that just randomly move, in *blue* in the figure. You need two kinds of submolecules (call then A and B), which when they meet – through the only authorized additive chemical reaction – form an A-B molecule (A is hydrophobic and B hydrophilic) whose two poles are connected by a small string. You need also to adjust the degree of repulsion between A and water and between B and water, the strength of the string of the A-B molecule, and the random component (akin to the thermal noise) to add on each of the intermolecular forces. Nevertheless, the final outcome turns out to be rather robust. The bilayer of B-A/A-B molecules will very naturally and spontaneously form just as for real cells.

Again, as for Varela's minimal cell, the closure turns out to be quite delicate to obtain. One very simple way to obtain it is to locate the source of A submolecules (the *pink dots* in the figure) in a singular point, so that the closed membrane will simply surround that source, the circular shape being the local minimal of the mechanical energy connecting all A-B together. Like in Varela's model, and somewhat paradoxically, the source needs to be circumscribed by the membrane for that same membrane to close on itself. However,

in contrast with this autopoietic model, once in place, the membrane cannot deteriorate, and thus, no further internal chemistry is required to endogenously produce what would be needed to fix it. Ultimately, this membrane should exhibit some selective channeling in and channeling out (akin, for some authors (Luisi 2002), to a very primitive form of cognition) providing its internal metabolism with the right nutrients and the right evacuating way out so as to facilitate the cell's self-maintenance. These two software models raise interesting questions for the biologists like: how are the molecular parts of the membrane generated (endogenously or exogenously) and is this cogeneration of the membrane and the internal metabolism the signature of minimal life?

Self-Replication of This Elementary Cell

Self-replication, or the ability of a system to produce a copy of itself on its own, is one of the essential characteristics that has most intrigued and impassioned disciples of artificial life, beginning with John Von Neumann. Biology, and in particular this faculty of self-replication, fascinated Von Neumann. For if we want to compare a cell to a computer and a genome to a code, we need to explain how the computer itself was able to be created out of this code. Let us follow the reasoning of this genius step by step, as it is the perfect illustration of an "artificial life" type of approach: no material realization but just pure functions or rules. Through a sequence of purely functional questions and showing an almost complete ignorance of actual biology, his reasoning led to a logical solution, the content of which retraces astonishingly closely those lessons we have since learned about the way biology functions. Von Neumann begins from the principle that a universal constructor C must exist, which, based on the plan of some kind of machine P_M (P the plan, M the machine), must be capable of constructing the machine M^P . This idea may be simply translated by $C(P_M) = M^P$. The question of self-replication that is then raised is, "Is this universal constructor capable of constructing itself?" In order to do so, it must, following the example of other construction products, have a plan of what it wants to construct; in this specific case, it is the

constructor's plan P_C . The problem is then expressed as follows: can $C(P_C)$ give $C(P_C)$ in order for there to be a perfect replication of the original? Von Neumann therefore realized that the question at issue is that of the fate of the construction plan, because if the constructor constructs itself, it has to add the plan itself to the product of the construction. Von Neumann proposed then allotting two tasks to the universal constructor: constructing the machine according to the given plan and thus adding the original plan to this construction. The constructor's new formula then becomes $C(P_M) = M^P(P_M)$. If the constructor applies itself to its own plan, this time the replication will be perfect: $C^P(P_C) = C^P(P_C)$.

The fascinating aspect of Von Neumann's solution is that it anticipated the two essential functions that, as we have since discovered, are the main attributions of the protein tools constituting the cell: constructing and maintaining this cell and also duplicating the code in order for this construction to be able to prolong itself for further generations. Starting with the ► [DNA](#), the whole ► [protein](#) machinery first of all builds the cell and then, by an additional procedure, duplicates this same DNA. Von Neumann did not stop at duplication, because, at the same time, he imagined how this same machinery could evolve and become gradually more complex as a result of random mutations taking place while the plan recopies itself. Von Neumann gave also a cellular automata solution of the problem in which each cell of the automata possessed 5 neighbors and 29 states, and around 200,000 cells were necessary for the phenomenon of self-replication to take place. Many years later, Chris Langton (Langton 1984, 1989), the organizer of the first conference on artificial life in 1989, proposed an extremely simplified version of this (8 states, but 219 rules remain necessary), although it still follows the pattern mapped out by Von Neumann. This automaton, shown in Fig. 6, incessantly reproduces a little motif shaped as a loop.

For many biologists, as opposed to Varela, Luisi, Ganti, and Maynard-Smith, life is not simply indissociable from but also essentially reducible to this capacity for self-replication. Nevertheless, they still need to explain how life

Artificial Life, Fig. 6 Langton's self-replicating cellular automata

can actually reproduce without an entire preexistent metabolic chemical machinery. Departing from the elementary cell introduced in the preceding section and in the interest of an unbroken narrative, let us imagine a simpler scenario leading to self-replication. The closed circuit of chemical reactions could be destabilized by some kind of disturbance, causing a growth in concentration of some of its constituents, including those involved in the formation of membranes. This would also be the case provided all the reactions of the metabolism turn out to be autocatalytic, entailing the exponential growth in the concentration of all its molecular elements (including again the membrane constituents). The membrane and the elements that it captures begin to grow (as illustrated in Fig. 7) until they reach the fatal point where the balance is upset. This is followed by the production of a new cell produced by and from the old one. When the new one comes, it quickly grows fast enough to catch up with the "generator" and "nursing" cell, as a chemical network is capable of some degree of self-regeneration due to its intrinsic stability; each molecule looks around for another that it can couple up to. This reconstitutes the natural chain reaction of the whole. The new membrane and the new chemical network reconstitute on their own by helping each other. Again, obtaining such duplication is far from obvious since, any cell being intrinsically stable, only a thermal but quite unnatural agitation would do the job.

Artificial Life, Fig. 7 The elementary minimal cell of Fig. 5 in a process of self-replication induced by the growing and the division of the chemical metabolic network

together with the membrane enclosing it. A lot of random thermal noise is here indispensable to destabilize the initial cell

Rather than this elementary form of chemical self-replication coupled to the physical self-replication induced by the growth and division of the membrane, life has opted for a more sophisticated physicochemical version of it, more promising for the evolution to come: self-replication by the interposing of an “information template.” Each element of the template can only couple itself with one complementary element. The new elements will as a whole naturally reconstitute the template they were attracted to, causing then the replication of the entire template. In biology, it is the extraordinarily emblematic double helix of DNA that acts as a template, shouldering the major role in the history of life—that of the first known replicator. Our elementary cell must now be internally equipped with this information template. Since the 1950s, Timor Ganti (2003) proposed the first minimum mathematical system,

named “chemoton,” represented in the Fig. 8. This is the first abstract computational protocell that we know, constructed by Ganti as the original ancestor of living organisms. It possesses three autocatalytic chemically linked subsystems: a metabolic network, a membrane, and an information template responsible for scheduling and regulating self-replication. All three grow exponentially until they are able to reproduce, and they depend on each other for their existence and stability. The metabolism feeds the membrane and the template, the membrane concentrates the metabolites, and the template mechanism dictates the reproduction of the whole. The triad ensemble is indeed capable of a whole synchronous self-replication and tries to computationally answer questions about the three subsystems and their interdependency, such as “how does the self-replication of the template automatically

Artificial Life, Fig. 8 The schematic representation of Ganti's chemoton. One can easily see the three autocatalytic subsystems: the metabolism, the membrane, and the information template, chemically coupled

accompany the self-replication of the whole.” This complex software object, the “chemoton,” has also become the topic of many software developments and experimentations and is emblematic of artificial life at its best.

Genetic Coding and Evolution by Mutation, Recombination, and Selection

In the information template introduced in the last section, each letter constituting it contributes to the code of a functional component essential to the cell and designed on the basis of that code – a protein. As soon as he hears anyone talking about code, the software specialist has, quite legitimately, to put his head in through the window, because it is to him and him alone that we in fact owe the metaphor of the genetic code. Since ► [Darwin](#) and thereafter throughout all evolutionary science, we have a good idea of what the last chapter of the history of life is. Doubtless what has stimulated most developments in “artificial life” (primarily from the point of view of engineering) is the fact that the genetic code can evolve through ► [mutation](#) and sexual crossing between the old

machines, evolving so as to produce new machines that are more and more efficient. Over the past 20 years, many of those developments into artificial life have been eager to show how beneficial this idea is for the research and the automated discovery of sophisticated solutions to complex problems. As illustrated in Fig. 9, this research can take place through a succession of mutations and recombinations operating at the level of the code, with the best solutions proposed being preserved in the next generation in order to be used for a new cycle of these same operations. The brute force of the computer is used to its full effect.

These are the same genetic algorithms that Dawkins used in his Darwinian crusade, when he developed his biomorphs. It should also be stressed that another element in Dawkins' program is that, when it is finally evaluated, the phenotype is not directly obtained from the genotype, as would be the case for classical optimization in a real or combinatorial space. In his work, the biomorphs are the product of a recursive sophisticated program, which is carried out starting from a given ► [genotype](#) to give a ► [phenotype](#). A great “semantic distance” is maintained between these genotypes and phenotypes, which reflect the long process of cell construction from the genetic code and the need for a sophisticated metabolism building the machine out of the code. In brief, this constant program, able to interpret the evolving genotype, is much more important for the complexity of the final outcome than the genotype itself. Similarly, a very prized derivative of these algorithms is genetic programming (Koza 1992), where the individuals now to be optimized are software codes.

Conclusions

Parallelism, functional emergence, and adaptability are the conditions necessary to allow these new biologically inspired artifacts to emerge, to “face the world.” We are jumping straight into the robotics branch of artificial life (Brooks 1991). The interfacing with the real world required by these robots needs a parallel information reception mechanism, because the environment subjects it to a constant bombardment of stimuli. They have

Artificial Life,

Fig. 9 Illustration of the genetic algorithms: the recurrent iterated sequence of selection, mutation, and recombination easily leads to an interesting solution of a complex optimization problem

to learn to organize and master this avalanche falling on their perceptions. They have to learn to build their own concepts, fed and stimulated by this environment, which, in turn, allows them to master it. The conceptual high-level cognitive processes are born out of motor-sensory interactions and serve to support them. Cognitive systems extend at new levels what the minimal cell in the primitive soup does, with a flow of matter and energy crossing straight through, maintaining itself by selectively integrating this influx to form a closed reactor network and the membrane enclosing it.

My conclusions are addressed to the three partners: the biologist, the engineer, and the philosopher. To the first, the outcomes of artificial life consist in bringing out what the computer and biology share intimately: an elementary way of working at the ultimate lowest level, but, which by the brute force of parallelism and incessantly repeated iterations, can make unknown and sophisticated phenomena to emerge at higher levels. The qualitative aspect of these simulations can give them new roles in the vast scientific register: use it for education, illustrate biological principles that are already understood, open up possible experiences of thought, play and replay multiple biological scenarios very quickly, titillate

the imagination by on-screen representations, call into question some of the ambiguously interpreted but commonly accepted facts, and, when detailed at most, be able to predict experimental measurements.

The second partner, the engineer, is vigorously encouraged to use the computer for what it is best at doing – this infinite possibility of trial and error. There is a perfect synergy, where both participants complement each other ideally: the engineer must bow to the computer in terms of calculating power, but this is compensated for by his judgment. Genetic algorithms, ant colonies, neural networks, and reinforced learning have enriched the engineer's toolbox.

Finally, for the philosopher, for each attempt at a definition of life, artificial life makes a real attempt to achieve a computerized version in conformity with this definition. For the skeptic, unhappy with this computerized "lining," the question now becomes how to refine his definition, to complete it, or to renounce the possibility that there is no definition that cannot be computerized. The other possibility, doubtlessly more logical but more difficult for many philosophers to accept, would be that life poses no problem for a computer snapshot since it is computational at its roots.

[Synthetic organelles](#)

Definition

An artificial organelle is a distinct functional sub-unit or sub-compartment of an artificial cell.

Artificial organelles serve to localize and spatially organize cellular components, separate competing chemical processes from each other, enhance the efficiency or specificity of chemical reactions, or perform other dedicated functions. Similar to biological organelles, artificial organelles may be generated through membrane encapsulation, phase separation, organization on, and association with membranes or other types of scaffolding. Artificial organelles improve and expand the capabilities of artificial cells and enable the realization of larger and more complex cellular structures.

History

In biology, organelles refer to specialized functional subunits of cells. In eukaryotic cells, organelles often specifically denote membranous compartments such as the nucleus, the endoplasmic reticulum, the Golgi network, mitochondria, and intracellular vesicle structures. In recent years, it has become clear, however, that liquid-liquid phase separation inside the cell can also give rise to organelles not bounded by membranes. With few exceptions, prokaryotes do not have internal membrane systems, but they also have distinct functional subunits or structures, which are referred to as prokaryotic organelles – for example, the nucleoid, flagella, carboxysomes, and other protein nano-compartments (Yeates et al. 2008; Agapakis et al. 2012).

Much work on artificial cells has initially focused on the encapsulation of biochemical reaction networks within membranous compartments, but did not consider sub-compartmentalization. The complex internal structure of extant cells shows, however, that cells are not simple “bags of enzymes,” and that their internal structure is important for their function. More recent artificial cell structures, therefore, involved the inclusion of artificial organelles (Göpprich et al. 2018), which were designed to perform a variety of different functions:

- 1) Compartmentalization of enzymatic pathways: Multienzyme pathways involve the interconversion of a substrate into a product over

multiple intermediate steps. Pathway intermediates may be lost by diffusion, via competing enzymatic reactions, or through reactions caused by unfavorable chemical conditions (Schoonen and Van Hest 2016). Compartmentalization of enzymes into artificial organelles has been used to address these issues: co-encapsulation of enzymes belonging to a pathway can protect intermediates from competitors, prevent diffusion, and ideally also provide the appropriate chemical environment (e.g., pH, ionic conditions). A variety of artificial organelle systems based on lipid vesicles and also polymersomes have been realized so far that demonstrate the benefit of sub-compartmentalization for several model enzyme pathways (Peters et al. 2013; Elani et al. 2014; Hindley et al. 2018; Reifenrath et al. 2020). There is also a considerable body of work on the creation of synthetic protein organelles that enable the localization of enzymatic pathways (Jordan et al. 2016; Sigmund et al. 2018).

- 2) Spatial separation of transcription and translation processes: In eukaryotes, transcription processes are localized to the nucleus, while translation takes place in the cytosol and the rough endoplasmic reticulum. In attempts to mimic the separation of these processes in the context of artificial cells, dedicated transcription, and translation organelles have been developed by several groups (Thiele et al. 2014; Aufinger and Simmel 2018; Niederholtmeyer et al. 2018). In biology, the emergence of a nucleus appears to be a consequence of the endosymbiotic origin of eukaryotes. Separation of transcription and translation by the nucleus enables splicing of eukaryotic transcripts before translation and facilitates fine-tuned gene regulation by localizing specific transcription factors to the nucleus. The nucleus is also the site of genome replication and plays an important role in eukaryotic cell division. Potentially, similar functional roles could be important for the development of more complex artificial cells.
- 3) Bioenergetic organelles for the generation of chemical fuels: One of the major tasks for the

realization of autonomous artificial cells is the establishment of energy harvesting processes. Extant cells generate chemical fuels by converting the energy stored in an electrochemical membrane potential into energy stored in chemical bonds. These processes require membranes for the establishment of an electrochemical gradient and membrane-bound enzymes such as ATP synthase that can perform the conversion. While in prokaryotes these processes are localized to the cell membrane, eukaryotes harbor bioenergetic organelles such as mitochondria for respiration and chloroplasts for photosynthesis. These organelles are presumed to have enabled eukaryotic genomes and cell sizes to grow far beyond those of prokaryotes and are thus made responsible for the complexity of eukaryotic life forms (Lane and Martin 2012). Several artificial cell systems have been realized so far that contain bioenergetic organelles and were thus capable of a limited form of autonomous energy harvesting and ATP generation (Lee et al. 2018; Pavan Kumar et al. 2018; Göpflich et al. 2019).

[Aeronautics and Space Agency of FFG; Agentur für Luft-und Raumfahrt der FFG; Austrian Space Agency, Austria](#)

Definition

The Aeronautics and Space Agency (ASA) of the FFG (Forschungsförderungsgesellschaft) is the gateway to the international aerospace industry for Austria's industry and science sectors and aims to strengthen their international standing in these key technologies. The agency supports the participation of Austrian researchers in international and bilateral aerospace collaborations and fosters the creation and development of international networks. It implements Austrian aeronautical space policy and represents Austria's interests in international aeronautical and space organizations.

The FFG's main focus is on managing the contributions of the Republic of Austria to the programs of the ► [European Space Agency](#)

([ESA](#)), and FFG is responsible for the management of the Austrian Space Applications Programme (ASAP), a bottom-up program targeted to space science, technology, space technology transfer, direct applications of space technology, and international cooperation.

History

The Space Research Institute of the Austrian Academy of Sciences was founded in 1970, and the Austrian Space Agency in 1972 (which was merged into FFG in 2004). Austria has been participating in ESA programs since 1975 and became a full member in 1987.

Bilateral cooperative projects have been undertaken in particular with the former Soviet Union, such as the development of Austrian instruments for space probes and missions. These projects include, for example, the two Venus probes, Venera 13 and 14 (1981–1982), the Vega 1 and 2 (1984–1986) missions to Halley's Comet, and the PHOBOS Mars probes (1988–1989). The highlight of bilateral cooperation with the former Soviet Union was the AUSTROMIR-91 mission – the flight of the first Austrian cosmonaut, Franz Viehböck, to the MIR space station. Other bilateral projects were, and still are, run in partnership with Norway, Sweden, France, Switzerland, and Germany.

Among other activities, FFG organizes annually since 1975 the well-known Alpbach Summer School that has a long tradition in providing in-depth teaching on aspects of space science and space technology with the aim of advancing the training and working experience of European graduates, postgraduate students, young scientists, and engineers.

Asgard, Archaea

Ricardo Amils
Departamento de Biología Molecular, Centro de Biología Molecular Severo Ochoa, Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Asgardarchaeota](#)

Definition

Asgard archaea also known as Asgardarchaeota is a superphylum of archaea which includes the closest prokaryotic relatives to eukaryotes. Lokiarchaeota, Thorarchaeota, Odinararchaeota, and Heimdallarchaeota phyla were the first members of the group, and new phyla have recently been incorporated. The general property of Asgard archaea is that their genomes contain genes that encode proteins detected previously only in eukaryotes: (GTPases, ubiquitin, profilin, gelsolin, regulated actin cytoskeleton, and membrane-remodeling proteins of the ESCRT type). Ecologically, they have been identified in very diverse environments: hydrothermal vents, rivers, and marine bays. The described Asgard archaea are generally obligate anaerobes, although some members can grow in the presence of O₂. In relation to their carbon source, some are autotrophs, others are heterotrophs, and some members are even phototrophs using a rhodopsin-like pigment to generate a proton gradient. The origin of the cellular complexity of eukaryotes is one of the major enigmas in biology. A favored scenario for eukaryogenesis is a syntrophic relationship between an Asgard archaea and unknown bacteria generating the nucleus and a posterior endosymbiotic incorporation of an Alphaproteobacteria to become the energy-generating system (mitochondria). This hypothesis was Lynn Margulis' most important contribution to evolution, and even though it was challenged by neo-Darwinists, the use of molecular biology techniques has proved its merit.

[Agenzia Spaziale Italiana](#); [Italian Space Agency](#)

Definition

The Italian Space Agency was established in 1988 to coordinate all of Italy's efforts and investments in the space sector that had begun in the 1960s. Today, ASI has a key role at the European level

where Italy is the third contributing country to the ► [European Space Agency](#).

Italy is directly involved in major European and international programs. It provides several elements for the International Space Station like the multipurpose logistic module (MPLM) used to transfer cargo with the US space shuttle, Nodes 2 and 3, and is participating within ESA in the European Automated Transfer Vehicle activities. ASI selected five astronauts flying either through bilateral cooperation or through ESA. Franco Malerba was the first Italian in space in 1992 onboard the STS 46 flight. Italy is involved also in many missions dedicated to planetology, astronomy, and exploration. It is playing a major role in the Cassini-Huygens mission, the ► [ExoMars](#) ESA mission, and many others. Italy is taking also a major share (65%) in the medium launcher program (Vega rocket) of ESA.

Beyond the headquarters in Rome, ASI has three bases and one center. “Luigi Broglio” Space Centre of Malindi, Kenya, was used to launch US Scout rockets with Italian satellites from oceanic platforms (the marine segment) up to 1988. Nowadays this base (the ground segment) is dedicated to receive data from satellites and launchers.

A stratospheric balloon launch base is located on a former airport in Trapani (since 1975). This base is, in particular, actively involved in trans-Mediterranean flights of research balloons.

In Matera, in collaboration with several institutions, ASI opened in 1983 a Space Geodesy Center dedicated to this discipline. Now this base is diverting its activities welcoming some technical activities required for robotic exploration.

Finally, an ASI Science Data Center (ASDC) was established in September 2000 for the management and analysis of scientific data collected by scientific satellites. This center is located in the ESA facility (European Space Research Institute-ESRIN) in Frascati, which is dedicated to the Earth observation.

Askja Caldera, Lunar Natural Analog

Definition

Askja (Google Earth coordinates: 65° 00' 41" N; 16° 44' 54"; and 1510 m elevation) is an active volcano situated in the remote center of Iceland, in the region called *Highlands of Iceland*. Askja consists of three nested calderas (depressions created by the collapse of volcanic edifices by emptying the magma chamber during paroxysmal eruptions) which cover a total surface of 45 km². Askja volcanic complex is located just 35 km north of the northern edge of the *Vatnajökull*, the largest ice cap of Iceland and of Europe, and today is part of the *Vatnajökulsþjóðgarður* (the Vatnajökull National Park). Since the 1960s, NASA selected this site for training the ► [Apollo mission](#) crews. Recently, there was a renewed interest for Askja as a Moon and Mars natural analog, for its spectacular exposure of regolith, subsurface ice deposits, and lava flows.

Overview

The Askja central volcano belongs to the Askja volcanic system (Trippanera et al. 2017). This site is located within the so-called North Volcanic Zone of Iceland which corresponds to the north-eastern branch of the north-Atlantic ► [midocean ridge](#) that crosscuts Iceland with a general NE-SW trend. The midocean ridge is here characterized by *oblique extension*, i.e., the direction of spreading

is oblique to the regional trend of the deformation. This created five *en echelon* spreading segments, each having a fissure swarm and an associated central volcano, from north to south: Theistareykir, Krafla, Fremrinámar, Kverkfjöll, and Askja.

The Askja central volcano is thought to have been active for the last 300,000 years and hosts three nested calderas within the basaltic *Dyngjufjöll* massif (e.g., Trippanera et al. 2017). The older one is the *Kollur* caldera which rim is partly obliterated by the largest 8-km diameter *Askja* caldera, which in turn contains the younger 5-km diameter *Öskjuvatn* caldera, which hosts today *Lake Öskjuvatn*. More than 175 eruptions (both effusive and explosive) during the last 7000 years have been identified on the field, more than 50 of which occurred in historical times, with the last ones occurring at the end of the 1920s. The most impressive eruption is the 29–30 March 1875 rhyolitic Plinian eruption that initiated the formation of the *Öskjuvatn* caldera. The explosive products were dispersed through Europe. Today, only a little fumarolic activity within the Askja caldera is observed, but the volcano is still active. This volcanic activity – which extended for 200–300 ka – created the *Dyngjufjöll* massif, which is the product of numerous interglacial, ice-confined subaqueous, subglacial, and emergent basaltic eruptions that produced an 800-m-thick sequence of tuffs, lapilli tuffs, hyaloclastite, lava breccia, and ► [pillow lava](#).

Askja location was selected by NASA in the 1960s to train its Apollo mission astronauts to “lunar analog geology.” The site was selected for two main reasons: the presence of large basaltic regolith deposits with an impressive similarity to the lunar landscapes (Fig. 1) and the remoteness of the place, which allowed the US army to easily control the place and avoid worried espionage activity by the Soviets. Still today, there are only two roads to access the site (open from June to October because of the adverse climatic conditions) with several rivers to cross, requiring specially equipped 4 × 4 trucks. NASA organized

Askja Caldera, Lunar Natural Analog, Fig. 1 Lunar-like regolith landscape at the summit of Askja caldera, August 2019. (Photo credit: O. Rocher)

two geological field trips in 1965 and 1967 with a total of 23 Apollo astronauts participating to various activities (Fig. 2), including Neil Armstrong, the first man on the Moon of Apollo 11, and Harrison Schmitt of Apollo 17, the only scientist (geologist) trained as an astronaut by the program.

More recently, there was a renewed interest in Askja local geology as a lunar and Mars natural analog. The site offers a wide range of opportunities for planetary analog research and operations in the context of lunar and Mars exploration. The *Holuhraun* lava flow field erupted in 2014 south of Askja, which is the largest fissural eruption in the last 230 years in Iceland, is now the privileged playground for testing new technologies of future Martian rovers and drones by The University of Arizona-funded RAVEN team (Rover–Aerial Vehicle Exploration Network).

As an environmental analog, the poorly consolidated, locally ice-rich pyroclastic deposits

of the *Dyngjufjöll* massif constitute proxies for understanding the lunar regolith composition and stratigraphy (Williamson et al. 2013). The channelized basalt flows at Askja are also a morphologic analog for the long and thick lava flows of *Mare Imbrium* on the Moon (Garry 2014), the landing site of several lunar past missions such as Apollo 15, 17 and more recently in 2013 of the Chinese *Chang’e 3* lander and lunar rover *Yutu*. The newest *Holuhraun* lava field appears as a platy-ridged terrain analog of those observed in *Athabasca Valles* and *Marte Vallis* on Mars (Tolometti et al. 2020; Voigt et al. 2020). Finally, the geomorphology of subglacial hyaloclastites (a volcanoclastic accumulation or breccia consisting of glass fragments formed by quench fragmentation of lava flow surfaces during subglacial extrusion) and Aeolian deposits at Askja provides clues to the interpretation of volcanic

landforms in the north polar regions of Mars and of subglacial deposits and chaotic terrain located at the periphery of Martian volcanoes (Williamson et al. 2013; Baker et al. 2021).

Finally, volcanic subsoils of Askja have been also studied to determine microenvironment variability and its impact in the diversity of microbial life (Rader et al. 2020). A maximum of diversity and abundance of microbial life in ash layers buried under surface pumices has been observed. This suggests a sampling strategy for Mars search of ancient life, by looking for undisturbed explosive volcanic ash that could maximize diversity and abundance of different bioindicators.

Acronyms

ASPAST

Definition

The Peruvian Association of Astrobiology, ASPAST (Asociación Peruana de Astrobiología in Spanish), is the first Peruvian institution dedicated to astrobiology. Founded in 2013, it includes researchers, students, and disseminators of astrobiology from all over the country. ASPAST is proud to count among its members with very committed people from different disciplines with a transdisciplinary perspective, from natural sciences to social sciences. ASPAST is a nonprofit organization that works constantly to integrate astrobiology's goals with scientific dissemination like workshops organized in schools, the launch of stratospheric balloons for experimental purposes, as well as conducting conferences, online courses, and participation in scientific meetings.

Minor planet; Planetoid; Small Solar System body

Definition

An asteroid is an irregularly shaped rocky body orbiting the Sun that does not qualify as a planet or

a dwarf planet under the International Astronomical Union's (IAU) definitions of those terms introduced in 2006. In contrast to planets and dwarf planets, asteroids do not have sufficient mass for their self-gravity to overcome rigid body forces and assume a hydrostatic equilibrium (nearly round) shape. In contrast to comets, asteroids are inert bodies that do not display a coma of gas and dust (although a few objects originally classed as asteroids have subsequently been found to display cometary activity). Very small objects with a size of less than about 10 m are normally referred to as meteoroids.

Overview

The first asteroid, 1 Ceres, was discovered in 1801 by the Italian astronomer Giuseppe Piazzi, quickly followed in succeeding years by the discovery of 2 Pallas, 3 Juno, and 4 Vesta. Ironically, Ceres is now classed as a dwarf planet under IAU Resolution B5 of 2006, and Pallas and Vesta are candidates for transfer to this new category of dwarf planets. Since about 1850, the discovery rate has increased dramatically, especially in recent years, leading to the current tally (September 2021) of over 585,000 numbered asteroids. An asteroid is assigned a permanent designation, i.e., a sequential number, once its orbit has become accurately established through a sufficient number of astrometric observations.

Asteroids and comets are considered to be remnant bodies from the epoch of planet formation. Planet embryos, roughly lunar-sized bodies, formed in the protoplanetary disk about 4.5 billion years ago via the accretion of dust grains and collisions with smaller bodies (kilometer-sized planetesimals). A number of planet embryos succeeded in developing into the planets we observe today; the growth of other planet embryos and planetesimals was terminated by catastrophic collisions or a lack of material in their orbital zones to accrete. Most asteroids are thought to be the fragments of bodies that formed in the inner Solar System and were subsequently broken up in collisions. Comets and related icy bodies are thought to have accreted in the cold, outer regions of the protoplanetary disk where volatile

materials, such as water and carbon dioxide, were abundant as ices.

Most numbered asteroids are in the main asteroid belt between the orbits of Mars and Jupiter. The existence of the main belt is thought to be due to the collisional fragmentation of remnant planet embryos and planetesimals that were prevented from accreting into planets by the gravitational perturbations of the nearby massive planet Jupiter.

Main-belt asteroids (here we include Ceres, which has been reclassified as a dwarf planet – see above) consist largely of silicates and metals and come in all shapes and sizes up to about 1,000 km in diameter. Table 1 lists physical data for the first ten asteroids discovered. Large asteroids with diameters of several hundred km tend to be roughly ellipsoidal, but smaller objects generally have very irregular shapes. Asteroid surfaces appear to consist of loose dust mixed with gravel and boulders (regolith), whereby there is evidence that the regolith of km-sized bodies is coarser and less dusty than that of large main-belt asteroids.

Asteroid Dynamical Groupings

Asteroids are classified dynamically according to their orbital elements (semimajor axis, period, inclination, eccentricity, etc.). The most significant grouping of asteroids is the main belt, between about 2.0 and 3.5 astronomical units (au, the mean Sun-Earth distance) from the Sun. The main belt is populated by millions of asteroids, some 585,000 of which have been assigned sequential numbers to date.

A number of asteroid families exist in the main belt. Family members have very similar dynamical characteristics and may be fragments from relatively recent (relative to the history of the Solar System) collisions. For example, there are large families associated with the main-belt asteroids 4 Vesta, 8 Flora, and 10 Hygiea (Table 1). In these cases, the families presumably arose as the result of cratering events that gave rise to ejecta from the surfaces of the large asteroids. In other cases, precursor asteroids were apparently completely broken up. In both scenarios, the result

Asteroid, Table 2 Selected asteroid dynamical groups

Dynamical category	Semimajor axis [au]	Approx. no. known ^a	Notes
Trans-Neptunian objects (TNOs) ^b	>30	2,600	
Centaurs ^b	5.2–30	1,000	Possibly TNOs whose orbits have been perturbed by Neptune
Jupiter Trojans	5.05–5.4	10,000	Associated with the Lagrangian points of Jupiter's orbit
Main belt	2.0–3.5	1.1×10^6	5.85×10^5 <i>numbered</i> asteroids
Amors ^c	>1	11,000	$1.017 < \text{perihelion} \leq 1.3$ au
Apollos ^c	≥ 1	13,400	Perihelion ≤ 1.017 au
Atens ^c	<1	2,100	Aphelion ≥ 0.983 au
Inner-Earth objects (Atiras) ^c	<1	26	Aphelion <0.983 au

^aThe listed approximate numbers of known objects are valid as of September 2021; these numbers increase rapidly with time as new objects are discovered. For more details and updates, see the Minor Planet Center web site <https://www.minorplanetcenter.net/iau/lists/MPLists.html>

^bTNOs and Centaurs are distant icy bodies that may have much in common with comet nuclei

^cThe orbital characteristics of the different classes of NEAs are defined with respect to the Earth's perihelion (0.983 au) and aphelion (1.017 au) distances

is a family of fragments with similar orbits (and dust particles that probably contribute to the cloud of dust associated with the ecliptic plane and give rise to the zodiacal light). In most cases, the family members have very similar compositions.

Other major dynamical groups are described below and listed in Table 2.

Jupiter Trojans are asteroids that are trapped in dynamically stable zones 60° ahead of and behind Jupiter in its orbit. The stable zones are associated with the L4 and L5 Lagrangian points of Jupiter's orbit. There are some 10,000 known Jupiter Trojans orbiting between about 5.0 and 5.4 au from the Sun.

Trans-Neptunian Objects (TNOs) are very distant, presumably icy, bodies with semimajor axes larger than 30 au. Most TNOs are classed as asteroids according to the formal definition of an asteroid given above, but in terms of their physical characteristics, they may have more in common with comets. The first TNO was discovered in August 1992; some 2,600 have been discovered since.

The Centaurs have orbits between that of Jupiter and the TNOs. Centaurs are possibly objects that originated as TNOs but due to perturbations by Neptune are now in orbits that bring them

closer to the Sun. The number of known Centaurs is currently around 1,000. A few Centaurs have been observed to display comae and are classed as both asteroids and comets. TNOs and Centaurs are of particular scientific interest because they have been subject to less thermal alteration and processing than main-belt asteroids and may contain well-preserved primordial material from the epoch of formation of the Solar System.

Near-Earth asteroids (NEAs) are asteroids that are thought to originate in the main belt but which now have highly evolved orbits with perihelion distances of less than 1.3 au. NEAs are further categorized dynamically as Amors, Apollos, Atens, or Atiras (also referred to as inner-Earth objects – IEOs), according to the semimajor axes, aphelion and perihelion distances of their orbits (Table 2). The orbits of NEAs may evolve to intersect that of the Earth. Interest in the population of NEAs is focused mainly on the associated impact hazard (see below), but close approaches of NEAs to the Earth facilitate detailed telescope observations, including radar investigations, which provide insight into the characteristics of asteroids in general. Furthermore, the rendezvous missions, NEAR-Shoemaker, Hayabusa, Hayabusa 2, and OSIRIS-Rex, have provided a wealth of data on

Asteroid, Fig. 1 Near-Earth asteroid 433 Eros was the target of the NASA NEAR-Shoemaker spacecraft in 2000–2001. Eros is 34 km in length and of taxonomic type S. The large number of impact craters indicates an age of 1–2 Gyr. (Credit: JHUAPL, NASA)

the NEAs 433 Eros (Fig. 1), 25143 Itokawa (Fig. 2), 162173 Ryugu, and 101955 Benu (Fig. 3), respectively.

The Taxonomic Classification and Mineralogy of Asteroids

Sunlight incident on the surface of an asteroid suffers absorption in particular wavelength bands depending on the minerals present; reflected light therefore carries a spectral signature of the mineralogical composition of the asteroid's surface. Attempts have been made to classify asteroids according to details of the absorption features in their optical reflection spectra observed with astronomical telescopes. A number of classification schemes have been devised based on letters of the alphabet (e.g., Bus and Binzel 2002; DeMeo et al. 2009; Tholen and Barucci 1989). For example, a very common spectral or taxonomic type is S, originally intended to signify a stony or “siliceous” object. Another common type is C,

Asteroid, Fig. 2 Near-Earth asteroid 25143 Itokawa was the target of the Japanese Hayabusa spacecraft in 2005–2006. Itokawa is 535 m in length and of type S. Itokawa, which lacks craters, is much younger than Eros and may be an aggregate of components weakly bound by gravity or “rubble pile.” (Courtesy of JAXA)

Asteroid, Fig. 3 Near-Earth asteroid 101955 Benu was the target of the NASA OSIRIS-REx spacecraft launched in September 2016, which reached Benu in August 2018. Benu is surprisingly spheroidal in shape and has a diameter of some 500 m. It is a B-type asteroid and has a much rougher surface than anticipated from ground-based observations. (Credit: NASA)

originally signifying carbon rich or “carbonaceous.” Other letters, which are in common use, are M for metallic and V for Vesta-like. As the inventory of asteroid spectral data grew, and more

distinct spectral types were discovered, the taxonomic alphabet had to expand to incorporate more letters. Thanks to the improved sensitivity of modern astronomical instrumentation, it has become possible to identify subtle differences in spectral features within the classical taxonomic types, leading in some cases to the addition of small letters after the class letter to signify subclasses, e.g., Cb, Sq, etc.

Basic Methodology

Our knowledge of the physical properties of asteroids derives primarily from astronomical observations in various spectral ranges, using both ground-based and space-based telescopes. Information on rotation rates and shapes can be obtained from observing the variation of the brightness of reflected sunlight from an asteroid’s surface as it rotates. Information on mineralogy can be derived from spectroscopic observations, primarily in the visible and infrared regions of the spectrum. Observations in the mid-infrared, or thermal-infrared, spectral region provide information on surface temperatures and allow sizes to be calculated. A powerful method for the derivation of asteroid physical properties is radar. Analysis of radar echoes from asteroids provides precise information on position and velocity and therefore orbital parameters, and in some cases radar

imaging can reveal details of surface structure, and provide information on size, shape, rotation rate, and composition. Unfortunately, the use of radar is restricted to objects that make close approaches to the Earth or are relatively large.

Increasingly, rendezvous and fly-by space missions are contributing detailed information on selected asteroids. The data from such missions provide far more accurate information on the physical characteristics of the target objects than can be obtained from remote astronomical observations. On the other hand, although astronomical observations provide less detailed information, they have done so to date for many thousands of asteroids, while only a handful of asteroids have been visited by spacecraft. Astronomical observations and space missions are complementary approaches in asteroid research, with space missions providing “ground-truth” data that help to calibrate the results obtained from astronomical observations.

Key Research Findings

Water and Organic Material in Asteroids

The mineralogical associations listed in Table 3 include hydrated (water-bearing) silicates and organics. There is considerable evidence that hydrated minerals are also present on a number of M-type asteroids. Furthermore, water ice and

Asteroid, Table 3 Important asteroid taxonomic (spectral) classes

Class	Probable mineralogy	Associated geometric albedo ^a (p_v) range	Approx. % of all classified asteroids ^b
D, P	Carbon, organic-rich silicates	0.03–0.06	2
C, B	Carbon, organics, and hydrated silicates	0.03–0.1	30
M	Fe, Ni, and enstatite	0.1–0.2	2
S	Olivine, pyroxene, and metals	0.1–0.3	40
Q	Olivine, pyroxene, and metals	0.2–0.5	1
V	Pyroxene, feldspar	0.2–0.5	3
E	Enstatite, other Fe-poor silicates	0.3–0.6	1
X	Unknown (signifies otherwise unclassifiable featureless spectrum)	0.03–0.6	15

^aThe geometric albedo p_v is the ratio of a body’s (V-band) brightness at zero-phase angle to the brightness of a perfectly diffusing (Lambertian) disk with the same apparent size as the body

^bEstimated from the data of Bus and Binzel (2002) and Tholen and Barucci (1989). Note that discovery and observation bias against objects with dark surfaces implies that the distribution of taxonomic classes in the known population may not be representative of the entire asteroid population

organic material have been detected on the surface of the main-belt C-type asteroid 24 Themis (Campins et al. 2010; Rivkin and Emery 2010) and since on many other asteroids (Rivkin et al. 2015). The fact that many asteroids evidently carry significant amounts of water and organic materials may be relevant to questions concerning the origin of water and life on Earth. It is widely believed that bodies similar to asteroids and comets contributed to the early Earth's inventory of water and organics, but there is currently no consensus as to when or how.

A point of current debate is whether Earth's water was provided primarily by asteroidal material from the outer main belt at the time of formation of the Earth or whether comets and asteroids contributed water-bearing material at a later stage after the Earth had formed and cooled. Measurements indicate that the hydrogen isotopic ratio D/H in most of the comets for which such measurements have been made is an order of magnitude higher than that of protosolar material, but this significantly exceeds the factor of 6 enrichment of the Earth's oceans. On the other hand, the D/H ratio of carbonaceous chondritic asteroidal material is compatible with that of the Earth's oceans. Therefore, at face value, the D/H evidence appears to argue against a dominant post-formation water contribution from comets.

Investigations of the composition of meteorites, which are thought to originate in asteroids, indicate that carbonaceous chondritic asteroidal material contains up to 10% by mass of water (Drake and Righter 2002; Morbidelli et al. 2000). Therefore, asteroidal material, in the form of planet embryos from the outer main belt incorporated into the forming Earth (Morbidelli et al. 2000), may have contributed much of the Earth's water. Alternatively, hydrogen present in material similar to enstatite chondrite meteorites, incorporated into the growing proto-Earth, could account for most of its present-day water (Piani et al. 2020). While on the basis of current knowledge, e.g., comparisons of isotope ratios and noble gas ratios, it appears unlikely that comets or known asteroid types bombarding the Earth after the formation phase could have contributed significant water (Drake and Righter 2002), the debate

continues to the present day. For example, Lis et al. (2019) present evidence that hyperactive comets, such as 46P/Wirtanen, may have D/H ratios similar to that of the Earth's oceans.

In the case of organic material, a postformation source is required because it seems significant quantities of organics could not have survived on the Earth until formation was complete and the Earth had cooled. The most plausible source of organic material is therefore the flux of asteroids and comets that deposited material on the Earth after the formation phase. Some 100 amino acids have been detected in meteorites (e.g., the Murchison meteorite), and it is widely believed that many comets and asteroids carry amino acids and other organic molecules.

The Densities and Structure of Asteroids

Reliable estimates of density are difficult to obtain, since techniques for obtaining accurate masses and sizes of asteroids are complex and subject to large uncertainties. There are various methods of determining asteroids masses (see Britt et al. 2002 for a review), which all require measurement of the asteroid's gravity field by means of, for example, a spacecraft, observations of the perturbations of the orbits of other asteroids or Mars (applicable to large asteroids only), or observations of a satellite or companion asteroid by means of precision optical or radar observations. Asteroid sizes can be determined from, for example, spacecraft, thermal-infrared measurements (see Harris and Lagerros 2002 and Delbo' et al. 2015 for reviews, and the section on asteroid physical properties below), radar observations (see Fig. 4), polarimetry (e.g., Delbo' et al. 2007), and occultation observations.

Density estimates for just a few hundred asteroids are available to date. An important finding is that asteroid bulk densities tend to be significantly lower in general than expected from measurements of meteorites and terrestrial analogues of asteroid material ($2\text{--}8\text{ g cm}^{-3}$). In fact the bulk densities of some asteroids appear to be similar to that of water (1 g cm^{-3}), implying that these bodies must be highly porous. Such results and those from rendezvous missions provide convincing evidence that some asteroids, e.g., 25143

Asteroid, Fig. 4 Radar images of binary near-Earth asteroid 1999 KW₄ (left-hand row of three frames) received at the Goldstone 70-m antenna in May 2001. Each image has a resolution of 19 m/pixel and is a time exposure spanning several hours, showing the motion of the secondary relative to the primary. Due to the complexities of radar

imaging, these three images do not show true relative sizes or shapes of the components. The right-hand frame shows a computer model of the system in which the two components are seen to scale. The diameters of the primary and secondary bodies are 1.5 km and 0.5 km, respectively. (Images courtesy of L. A. M. Benner, NASA/JPL)

Itokawa (Fig. 2), 162173 Ryugu, and 101955 Benu (Fig. 3), are aggregates of components of various sizes weakly bound by gravity, or “rubble piles.” An asteroid that has been shattered by collisions with other objects may survive under the collective weak gravitational attraction of the resulting fragments as a cohesionless, consolidated rubble pile.

The rubble-pile idea leads to a natural explanation for the existence of the many binary asteroid systems or asteroids with natural satellites (moons) that have been discovered (see Fig. 4 for an example). The spin rates of asteroids can be modified by dynamical phenomena, such as the close approach to a planet, or the reflection and/or absorption and thermal reradiation of sunlight. If a loosely bound rubble pile is spun up sufficiently, it can shed mass that may form a companion body or moon gravitationally bound to it. Computer simulations have demonstrated the credibility of binary asteroid production via the spin-up and rotational breakup of a rubble pile (Walsh et al. 2008).

Near-Earth Asteroids and the Impact Hazard

As a result of subtle thermal effects and the very strong gravitational field of Jupiter, small main-belt asteroids can drift into certain orbital zones from which they may be ejected under the influence of Jupiter into the inner Solar System. As a result, there exists a population of near-Earth asteroids with orbits that can cross that of the Earth. Comets can also collide with the Earth, but the risk of a comet impact is thought to be

much lower than that of a NEA impact (although given the potentially high relative velocity, the effects in the case of a comet impact could be much more devastating).

The phenomenon of collisions in the history of our Solar System is very fundamental, having played the major role in forming the planets we observe today. Asteroids and comets may have contributed to the delivery of water and organic materials to the early Earth necessary for the development of life, but later impacts probably played a role in mass extinctions, and they currently pose a small but significant threat to the future of our civilization. Collisions of objects with the Earth have taken place frequently over geological history, and it is an irrefutable scientific fact that major collisions with the Earth will continue to occur at irregular, unpredictable intervals in the future.

Collisions of asteroids and comets with the Earth can have dramatic effects on the biosphere. A well-known example is the so-called Cretaceous–Paleogene (K–Pg) event, formerly known as the Cretaceous–Tertiary event, 65 million years ago, which is thought to have been caused by the impact of an object with a diameter of 10–15 km, bringing about the extinction of not only the dinosaurs but also more than 70% of all species living at the time. The idea that the K–Pg mass extinctions observed in the paleontological record were caused by the impact of a near-Earth asteroid was proposed by Alvarez et al. (1980), and given a great deal of credibility by the discovery of a 65-million-year-old circular impact structure

nearly 200 km in diameter centered near the town of Chicxulub on the Yucatan Peninsula, Mexico (Pope et al. 1991). The impactor must have had a diameter of at least 10 km and may have hit the Earth with a velocity of some 15–25 km s^{−1}. The results of such an event would have included the deposition of billions of tons of dust and aerosols into the stratosphere that would have spread around the world, dimming sunlight, and cooling the surface for many months. The ensuing climatic effects could have created a very stressful environment for life on the Earth’s surface for many years.

While past impacts have probably altered the evolutionary course of life on Earth, and paved the way for the dominance of mankind, we would now rather not remain at the mercy of this natural process. Can we protect our civilization from the next major impact? Various initiatives are being taken by space agencies, including ESA and NASA, and research groups around the world to identify potential future impactors, investigate their physical characteristics, and develop strategies to mitigate against impacts.

A number of observatories are operated specifically to discover near-Earth objects and establish their orbits. The main currently active asteroid search programs, such as Pan-STARRS, the Catalina Sky Survey, and ATLAS, are based in the USA (for a summary, see Melosh et al. 2019).

Many observers, including amateur astronomers, around the world contribute to the tracking of asteroids and submit their astrometric data to the Minor Planet Center in Cambridge, Massachusetts, which acts as a clearing house for asteroid position data and maintains databases of orbits.

As of September 2021, the number of known near-Earth objects is approaching 27,000, of which some 900 have diameters of 1 km or more; the total number of the latter, including as yet undiscovered objects, is thought to be about 1,000 (see below). A special term, “potentially hazardous asteroids” (PHAs), is reserved for those with diameters above a critical size and orbits that bring them within 0.05 au of the Earth’s orbit. PHAs are large enough to survive passage through the Earth’s atmosphere and cause extensive damage on impact. The diameter threshold qualifying an object as a PHA is traditionally set at 140 m for historical reasons but is currently under debate.

The estimated impact frequency of NEAs on the Earth depends on size. The impact frequency increases with decreasing size due to the size distribution of the asteroid population: There are many more small objects than large ones. The impact risk to the Earth from NEAs based on recent assessments (e.g., Harris et al. 2015; Harris and D’Abramo 2015) is summarized in Table 4.

Asteroid, Table 4 Estimated frequency and effects of asteroid impacts on the Earth

Impactor size (m) larger than	Mean impact interval (year)	Energy released (megatons TNT)	Crater diameter (km)	Possible effects/comparable event
30	150	2	–	Fireball, shock wave, and minor damage
50	1,000	10	≤1	Tunguska-type explosion or small crater
100	10,000	80	2	Largest H-bomb detonation
200	40,000	600	4	Destruction on national scale
500	140,000	10,000	10	Destruction on continental scale
1,000	500,000	80,000	20	Many millions dead, global effects
5,000	20 million	10 million	100	Billions dead, global climate change
10,000	100 million	80 million	200	Extinction of human civilization

The energy release estimates assume a density of 3500 kg m^{-3} (stony body) and an impact velocity of 20 km s^{-1} . The given impact intervals are statistical, for example, the probability of a 100-m or larger object impacting in the next 100 years is 1%, which is the same as the probability of such an object *not* impacting in 46,000 years.

Asteroid Physical Properties Relevant to the Impact Hazard

Accurate assessment of the impact hazard depends on knowledge of the size distribution and orbits of the NEA population. Which physical parameters are most relevant for mitigation considerations? Preventing a collision with a NEA on course for the Earth would require either total destruction of the object, to the extent that the resulting debris poses no hazard to the Earth or, perhaps more realistically, deflecting it slightly from its catastrophic course. In either case, accurate knowledge of the object's mass would be of prime importance. In order to mount an effective mission to destroy the object, knowledge of its density, internal structure, and strength would also be required. Deflection of the object from its course would require the application of an impulse or continuous or periodic thrust, the magnitude and positioning of which may depend on the mass and its distribution throughout the (irregularly shaped) body, the surface characteristics, and the spin vector, depending on the strategy deployed. Mitigation planning takes on a higher level of complexity if the Earth-threatening object is a rubble pile or binary system.

Since the observed brightness of an asteroid is proportional to its surface albedo and cross-sectional area, a very rough size estimate can be obtained from the observed brightness and knowledge of the asteroid's orbit. However, the albedo can have any value between 3% and 60% (Table 3), so the assumption of a typical albedo of, say, 15%, can lead to errors in diameter and mass of a factor of 2 and 8, respectively. While current estimates of the overall impact hazard are necessarily based on the assumption of a typical or mean albedo for NEAs, more accurate methods of

size determination are clearly necessary for accurate hazard estimation and mitigation purposes.

Telescope observations in the thermal infrared combined with knowledge of an asteroid's optical brightness offer a means of obtaining more accurate information on size and albedo (Delbo' et al. 2015; Harris and Lagerros 2002). Darker, low albedo, asteroids are less reflective in the visible spectral region and absorb more solar radiation; they are therefore warmer and brighter in the thermal-infrared spectral range. The opposite is true for high-albedo asteroids. The two different physical relationships governing visible and thermal-infrared brightness enable simultaneous solutions for size and albedo to be obtained. While the number of asteroids observed in the thermal infrared is still only a very minor fraction of the total known, this technique has provided the vast majority of size and albedo determinations to date. For example, surveys of the sizes and albedos of thousands of NEAs have been carried out by the NASA WISE (Wide-field Infrared Survey Explorer) and Spitzer infrared space telescopes. WISE was launched to Earth orbit in December 2009 carrying a 40-cm-diameter telescope and infrared detectors. WISE surveyed the sky for nearly 12 months in its cryogenic phase and observed a total of at least 584 NEAs, of which more than 130 were new discoveries. The NEO-WISE project, funded by NASA, continues to use the WISE spacecraft (albeit without cryogen and therefore with warm and less sensitive detectors) to discover and characterize NEOs. Before the Spitzer Space Telescope ceased operations in 2020, it enabled the diameters and albedos of over 2000 NEAs to be estimated. See Trilling et al. (2020) for a review of Spitzer's contributions to asteroid science.

Applications

Apart from the contributions that asteroid research provides to our understanding of the evolution of the Solar System, the formation of the planets and the origin of life on Earth, and the hazard posed by near-Earth objects, an area of interest inspired by the recent rapid development of the field is that of

asteroids as potential providers of raw materials for future space-faring generations. As described above, some asteroids carry significant amounts of water that could be extracted and used to sustain human activities in space. The constituents of water, hydrogen, and oxygen could be used as rocket fuel. Other asteroids contain large amounts of metals, e.g., platinum group metals, that are used in many applications in industry and for which there is an ever-increasing demand.

Future Directions

The rate of discovery of NEAs is now seriously outstripping the rate at which the population can be physically characterized. The NEA population is still largely unexplored. Telescope observations will continue to provide valuable information about the NEA population as a whole, but rendezvous missions are vital for probing the detailed characteristics of individual objects. To date only four NEAs have been visited by spacecraft (see above), but many more rendezvous missions to NEAs of different taxonomic types will be necessary before we can start to understand the diverse compositions, structure, and origins of NEAs and their relation to meteorites.

Mitigation of Hazardous Asteroids

At present, there is no general agreement on the most effective strategy to adopt in the case of a predicted impact. In the case of an object with a diameter below 50 m, the best course of action may be to simply evacuate the region around the predicted impact point (see Table 4), assuming there would be sufficient advance warning (only a small fraction of the asteroids in this size category have been discovered to date). For larger objects, a number of mitigation strategies may be considered, depending on circumstances. In 2004, ESA established the Near-Earth Object Mission Advisory Panel (NEOMAP) to study and prioritize proposals for planetary defense missions. NEOMAP concluded that a dual-spacecraft mission called Don Quijote, based on the kinetic-impactor method, should be given highest priority as the basis for ESA's participation in

NEO impact-risk assessment and reduction (NEOMAP report to ESA 2004). The kinetic-impactor method involves applying an impulsive force to the asteroid by means of a large mass in the form of a spacecraft accurately guided to the target at a high relative velocity. The change of momentum of the target asteroid depends on the porosity and the amount of ejecta produced in the impact (Fig. 5), predictions of which would require some prior knowledge of the asteroid's physical properties. To facilitate effective mission planning, the kinetic-impactor approach would require an initial reconnaissance mission to gather relevant physical data.

The NASA report to Congress (2007) on the surveying and deflection of near-Earth objects concluded that nuclear devices offer the most effective means of applying a deflecting force to

Asteroid, Fig. 5 Artist's impression of a kinetic-impactor spacecraft deployed to modify the orbit of a near-Earth asteroid. The second spacecraft at the bottom of the picture is orbiting the asteroid or "hovering" near it to observe the effects of the impact and monitor the altered trajectory of the asteroid. The scenario depicted derives from the Don Quijote mission, studies of which were commissioned by ESA in 2006. The European-led NEOShield project carried out detailed investigations of this and other promising deflection techniques. (Credit: ESA-AOES Medialab)

an asteroid. While they may offer the only feasible solution in desperate circumstances, e.g., in the case of very little advance warning, it is widely felt that the obvious political problems associated with launching nuclear devices and testing them in space seriously compromise the practicability of this technique. The NASA report concluded that the most effective nonnuclear option is the kinetic impactor.

Alternative approaches include the “gravity tractor” and “space tug.” The gravity tractor relies on the force of gravity between the target asteroid and a spacecraft hovering under power in close proximity to gradually modify the asteroid’s orbit. A significant advantage of the gravity tractor is that no contact with the target is required. The principle of the space tug is similar, but in this case, the spacecraft is physically attached to the asteroid’s surface and prior knowledge of surface characteristics would be necessary for effective mission planning. The gravity tractor and space tug are examples of “slow-push-pull” approaches that require sustained, reliable propulsion and sophisticated autonomous control systems to achieve the required amount of deflection, but may be promising techniques in cases in which there is sufficient advance warning (e.g., decades), the target is relatively small, and/or a very slight, precise deflection is required to prevent an impact on the Earth.

A unique research program funded by the European Commission and involving 13 partner organizations in six countries, including Russia and the USA, was established in 2012 to investigate deflection techniques in detail. The project, called NEOShield (Drube et al. 2015; Harris et al. 2013), investigated the feasibility of promising deflection options and carried out research into the mitigation-relevant physical properties of NEOs. A follow-on project, NEOShield-2, was funded from 2015 until 2017.

Endeavors such as those described above paved the way for two missions: the NASA Double Asteroid Redirect Test (DART: Cheng et al. 2018), a kinetic impactor, due for launch at the end of 2021 to the binary asteroid 65803 Didymos, and the ESA mission Hera (Michel et al. 2018), a

reconnaissance mission with the aim of carrying out a survey a few years later of the effects of the impact on the Didymos system. The aim of DART is to deflect the small secondary of the binary asteroid Didymos (primary diameter = 780 m), chosen so that the perturbation of the orbit of the secondary (diameter = 160 m) can be observed from ground-based facilities in 2022. DART will be the first mission to measurably alter the motion of an asteroid, and the first realistic demonstration of the kinetic-impactor deflection technique. Hera will obtain information needed for an accurate assessment of the feasibility and efficiency of the technique. At the time of writing, the European Commission is funding two research programs, NEO-MAPP and NEOROCKS, in which research relevant to the interpretation of DART and Hera data is being carried out.

Asteroids in Extrasolar Planetary Systems

The presence of asteroids and comets outside our Solar System cannot be confirmed by direct observation, but there is considerable evidence that such objects play a role in the formation and development of extrasolar planetary systems. Infrared observations have shown that many stars exhibit thermal emission in excess of that predicted for their stellar types. The excess thermal emission can be modeled in terms of surrounding dust disks heated by the star that may be the debris of asteroids and comets destroyed by collisions or close approaches to planets or the central star.

Data obtained with the Spitzer Space Telescope in the mid-infrared spectral region suggest that some extrasolar systems have multiple debris disks: warm disks analogous to the main asteroid belt and cooler outer disks possibly containing bodies analogous to the distant TNOs in the Solar System (for a review, see Chen et al. 2020). Attempts have been made to match the infrared spectra of extrasolar debris disks with spectra obtained from observations of comets and asteroids. In the case of the star HD 69830, which exhibits unusually intense emission from dust (Fig. 6), the best match appears to be materials found in P- or D-type asteroids (Lisse et al.

Asteroid, Fig. 6 Comparison of features in the spectra of the excess thermal emission from the star HD 69830 and the comet Hale Bopp. The similarity of the spectra strongly suggests that the dust in the debris disk around HD 69830 has a very similar composition to dust in the Solar System. Despite the similarities to the spectrum of Hale Bopp,

detailed analysis of the spectral signature of the dust around HD 69830 indicates that it probably originates from the breakup of asteroids (Lisse et al. 2007). (The figure is taken from Beichman et al. (2005) and is reproduced by permission of the AAS)

2007), which are very numerous in the outer main belt. The production of dust would follow the collisional breakup of asteroids, as invoked to explain the existence of asteroid families and zodiacal dust in the Solar System (see section on “Asteroidal Dynamical Groupings” above).

The discovery of extrasolar planets and debris disks strongly suggests that planet formation is a common phenomenon in the Galaxy. Knowledge gained from investigations into the processes of planet formation and development in our Solar

System will continue to stimulate and guide future research into similar processes taking place elsewhere in the Galaxy.

AsteroSeismology

Patrick Eggenberger
Geneva Observatory, University of Geneva,
Geneva, Switzerland

Synonyms

[Stellar seismology](#)

Definition

AsteroSeismology is the study of stellar oscillations aiming at determining the internal structure and global properties of stars. The oscillation patterns observed on the stellar surface result from waves that propagate into the interior of the star. The observation of these oscillations, done either by monitoring the variation of the star's brightness or of its radial velocity, offers therefore a unique means to probe the otherwise unobservable internal layers of stars and to help us in our understanding of the complex physical processes at work in stellar interiors.

Asthenosphere

Daniele L. Pinti
Geotop, Research Centre on the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Following the rheological subdivisions of the Earth, the asthenosphere is the viscous mechanically weak-ductile layer of the mantle. It lies

below the lithosphere, at depths between 100 and 200 km down to the transition zone (670 km). The asthenosphere plays a key role in plate tectonic movements and isostatic adjustments. The heat is transmitted by convection, and the thickness and viscosity of this layer controls the stress applied at the base of the lithosphere. This, in turn, influences the global tectonic style of the Earth and of any other terrestrial planet. The viscosity and the convective regime of the asthenosphere has also a control on the degassing history of a terrestrial planet and the evolution of its atmosphere.

Astrobiocentrism

Octavio A. Chon-Torres
Programa de Estudios Generales, Universidad de Lima, Lima, Peru

Definition

According to Chon-Torres (2020, 2021), astrobiocentrism is the way of understanding the place of human beings in the universe from an astrobiological perspective, overcoming the limitations of biogeocentrism, where the latter focuses on the understanding of life in an Earth-centric, carbon-based way (Chela-Flores 2001, 2009; Arétxaga 2004). (Note that the term “bio” is at the beginning of the word because that is how it appears in the original. In the specific case of astrobiocentrism, the word “astrobio” is

composed and at the beginning to evoke the astrobiological meaning to be expressed.) Some of the conceptual astrobiocentric pillars would be found in telompathy (Cockell 2005a, b, 2011) and the development of astroethics (Chon-Torres 2018). In it the debates on what we understand by a planetary, interplanetary, and multiplanetary ethics take place. It is an opportunity to put terrestrial ethics in context in an astrobiological landscape. In this concept, we would not only see ourselves as planetary citizens, but as citizens who share a moral community that despite having differences on how to manage or conduct an off-Earth society promotes dialogue and consensus for peaceful coexistence (Chon-Torres and Murga-Moreno 2021).

Definition

Astroethics is the study of ethical questions in connection with astrobiology.

Overview

In addition to being concerned with the same ethical issues as science and academia in general, for instance research ethics, discrimination, etc., astroethics also includes questions that are particular to astrobiology or have an added twist or dimension when applied to astrobiology. Among the key issues, we find the following:

- The moral for status of extraterrestrial life and its implications, for example, planetary protection and experimentation.
- How to interact with extraterrestrial life, including a wide range of issues ranging from what kind of experiments would be acceptable on different types of extraterrestrial life-forms,

to who should speak for Earth when interacting with extraterrestrial intelligent life.

- How to handle risks to humanity and other Earth life when interacting with extraterrestrial life, including risks of contamination in connection with Earth return missions and the retrieval of extraterrestrial material to Earth, and risks in connection with interstellar communication.
- How to balance conflicting interests, including conflicting interests regarding planetary protection between astrobiology, commercial interests, and groups who perceive space as a frontier that needs to be conquered, conflicting interests regarding the protection of space analogue sites on Earth between astrobiology and commercial and political interests; conflicting interests regarding the placement of telescopes between astrobiology, environmental concerns, and indigenous culture; and conflicting interest regarding public funding between astrobiology and other scientific as well as nonscientific competing projects.
- How to communicate with and involve the general public, including how to communicate results and possible interpretations of results to the public in a way that is transparent, but also accurate and that minimizes the risk of misinterpretation and inflated expectations while maintaining public trust in astrobiology and in science in general and avoid fuelling conspiracy theories (Almár and Race 2011; Chon-Torres 2018; Gartrelle 2015; Neal 2014).

Here follows short descriptions of the current most intensely debated issues in astrobioethics:

The Moral Status of Extraterrestrial Life

The moral status of extraterrestrial life is a question that is very much debated, both as a general question and, in particular, in connection with planetary protection. Here follows a short description of the main contestant theories regarding who or what has status as moral objects (i.e., who's interests have to be considered by a moral agent),

together with their implications for astrobiology (see also Persson 2012).

Anthropocentrism is the idea that only humans can be moral objects (e.g., Carruthers 1994; Descartes 1960; Kant 1998; Smith 2009). Historically, this has been the dominating answer to the question of moral status on Earth, though presently it is losing ground due to advances in both ethics and biology. Its implications for astrobiology depend primarily on the grounds for the theory. If only humans are considered moral objects on Earth due to us belonging to the same species, then no extraterrestrial life will count since independently of what other properties they have, they will not belong to the human species. If humans are considered the only moral objects on Earth because we are assumed to be the only species on our planet that possess a particular property (other than just belonging to a particular species), for example, a certain level of intelligence, then it is at least in theory possible that we will at some point encounter extraterrestrial life that has to count as moral objects according to anthropocentrism. As long as we do not expect to find intelligent extraterrestrial life in our solar system, this theory will only be relevant in connection with SETI and METI and in connection with the possibility that Earth in the future will visit or be visited by intelligent entities from other solar systems. Whether nonbiological intelligence counts according to this theory, depends on its exact basis for moral status. If intelligence is used as the sole basis, they will count.

Biocentrism is the idea that all living organisms count as moral objects (e.g., Goodpaster 1978; Schweitzer 1989; Taylor 1986). For astrobiology, this means we might have to consider what kinds of studies we can perform on extraterrestrial organisms, as well as on extremophiles on Earth. A particular challenge when applying biocentrism to extraterrestrial life is to determine what counts as life. For planetary protection, a biocentric perspective would create an interesting dilemma, since, on one hand, it means that all extraterrestrial life, including microbes, need protection that goes beyond their value as study objects, while on the other hand, it might be difficult to motivate mass killing of Earth microbes (i.e., cleaning and

sterilization of spacecraft, landers and equipment) in order to protect merely possible extraterrestrial life. Nonbiological intelligent entities will not count according to biocentrism.

Sentientism is the idea that all and only sentient life has moral standing (e.g., Regan 1983, 2001; Singer 1993, 1995). “Sentient” in this context is often defined as being able to feel pleasure and displeasure, and to have conscious experiences. It is sometimes explained as having a subjective perspective from which things can go better or worse, or as experiencing sensory data contrary to just receiving and acting on them. Sentientism is often considered the most philosophically plausible of the contestant theories and it is increasingly gaining influence in human-animal relations on Earth. When applied to extraterrestrial life, it may be difficult to determine whether an extraterrestrial entity is sentient, however, especially if it differs considerably from sentient life-forms as we know them on Earth. As long as we do not expect to find sentient life in our own solar system, and as long as we do not plan to travel to other solar systems, this theory will only be relevant for questions of back contamination, where sentient Earth life could be affected by alien biological material, or in connection with interstellar communication, that according to some critics may put the entire Earth biome at risk. For sentientism, nonbiological sentient entities will count exactly in the same way as biological sentient organisms.

Ecocentrism is the idea that not only individual organisms, but also holistic entities such as species, ecosystems, or entire biospheres have moral standing (e.g., Callicott 1986, 1999; Johnson 1991, 1992; Rolston 1986, 1999). The impact of this theory on astrobiology depends on which version of the theory one considers. According to one common interpretation, all environments have moral status, even if they do not contain life (Rolston 1986). According to another interpretation, called Land Ethics, extraterrestrial entities, including living organisms, cannot count at all since they are not part of the same living community as life and environments on Earth (Callicott 1986). Nonbiological intelligence will not count according to any of these interpretations of the theory.

Interstellar Communication

Another center of attention within astroethics is how we should react to messages from extraterrestrial civilizations and whether we should risk revealing our existence to extraterrestrial civilizations by active messaging, either as a response to their messages or on our own initiative.

The question of what to do if we receive a message from an extraterrestrial intelligence is rather complicated, not least due to the great uncertainties involved in the decision. It has been pointed out that decoding, or even receiving such a message may be dangerous (Neal 2014). It may contain harmful code that can infect our computers (Musso 2012), or information or misinformation that might (intentionally or unintentionally) disrupt human society by creating unrest or conflicts among the population of Earth, or it may (intentionally or unintentionally) lead us to self-destruction by containing instructions for how to construct very potent technology that we are not ready to handle in a safe way (Musso 2012). In addition to these concerns, there are also concerns about who should get access to the information (Wisian and Traphagan 2020). The possibility that the information is very valuable, maybe of a kind that would provide the reader with a strategic military or economic advantage on Earth, may lead to conflicts about who has the right to the information.

The next question regards whether we should actively transmit messages to outer space, either on our own initiative or as an answer to a message from an extraterrestrial civilization. If we do, we also need to discuss who should get to speak for Earth (Wisian and Traphagan 2020), and what to say. What kind of impression do we want to give of Earth and its human population? Do we want to be completely open about the conditions on Earth and what is going on here, or do we want to look more powerful or more peaceful than we are?

The issue that has gained the most attention in connection with interstellar communication is whether we should do it at all and risk revealing our existence, our location, and possibly other information about ourselves, when we do not

know if the potential receivers are friendly or not (e.g., Atri et al. 2011; Neal 2014). Critics argue that it is both imprudent and immoral to expose humanity and other Earth life to such a risk.

Those in favor of messaging extraterrestrial intelligence (METI), on the other hand, like to point out that the probability that the signals will be detected is very small (Zaitsev 2011), that we already transmit radio signals and have done so for some time, and that some of these signals are even stronger than those used by METI initiatives (Atri et al. 2011; Shostak 2013; Vakoch 2016; Zaitsev 2011), that an alien civilization that is so advanced that it can easily destroy us, can easily find us through other means (Zaitsev 2011), and that if a civilization is so technologically advanced that they can detect us and destroy us if they want, they will probably also be correspondingly more ethically mature and thus not be a threat (Musso 2012). Some of the proponents of active messaging also argue that we need to weigh the risks against possible advantages (de Vladar 2013) and against the risks we run by isolating ourselves (Vakoch 2016). The relevance and plausibility of these defenses are contested by those who argue for a low profile.

There are also a number of suggestions for how to handle the risk associated with messaging to potential extraterrestrial civilizations. Shuch and Almér (2007) recommend a cost-benefit analysis and input from international expert groups. Atri et al. (2011) suggest a protocol for messaging and input from outside the METI community and from different cultures.

Some criticize METI for being anthropocentric (e.g., Atri et al. 2011). Traphagan (2019) argues that METI is a form of scientific study that involves sentient beings as subjects and therefore should need approval from an ethical review board.

Definition

This encyclopedia defines astrobiology as the study of the origin, evolution, and distribution of life in the universe (see Preface). Such studies, or some part of them, have also been referred to as exobiology or bioastronomy, and at the present time, these terms can be considered synonymous. Although it has been stated that astrobiology is a science without a subject (since life outside the Earth remains undiscovered), in fact there is a vast and growing volume of research in fields included in the present encyclopedia.

Overview

Thus, although the physical and chemical processes that led to the origin of life on Earth are still far from understood, they clearly involve,

inter alia, the nucleosynthesis of chemical elements including carbon that are essential for life; the formation and evolution of the Sun and ► [Planets](#), including the delivery of water and organic material to the ► [Earth](#); prebiotic chemical processes; and the nature and evolution of the early Earth's atmosphere, crust, and interior. Furthermore, the study of the evolution of life and ultimately the development of ► [Intelligence](#) on our planet requires research, for example, in biochemistry, biophysics, microbiology (including life in environments that seem extreme by human standards), and ► [Genetics](#).

There is also the question of whether life exists elsewhere in the solar system or at other locations in the universe. These issues are addressed in the Encyclopedia of Astrobiology through entries characterizing various bodies in the solar system (particularly the existence of water, the universal solvent of terrestrial life), current knowledge concerning planets around other stars (extrasolar or exoplanets), how life might be identified beyond the Earth (biosignatures or ► [Biomarkers](#)), and space missions to investigate these topics.

Moreover, many questions relevant to astrobiology have in fact been asked by humanity throughout recorded history and certainly before that. In consequence, the Encyclopedia includes a section on History of Science, which includes theories on the origin and evolution of life and on the possible multiplicity of habitable worlds from classical Greek and Roman times, from the Islamic world, from ancient Asia, and from pre-Columbian America.

Lastly, what is the future of life, at least on Earth? Entries concerning ► [Artificial Life](#) are included which address some of these questions.

Astrobiology (IAU Commission)

William M. Irvine
 Department of Astronomy, University of
 Massachusetts Amherst, Amherst, MA, USA

Definition

The activities of the International Astronomical Union (► [IAU](#)) are mostly carried out within Commissions, grouped in turn into Divisions. The scope of the IAU Astrobiology Commission, within Division F (Planetary Systems and Astrobiology), is the study of the origin, evolution, and distribution of life in the universe. In this context, astrobiology encompasses the search for extant life, evidence of past life, or evidence of prebiotic chemistry on solar system bodies, including Mars, Europa, Titan, and Enceladus; the search for planets around other stars and potential spectroscopic evidence for habitability and biological activity; the origin of the biogenic chemical elements and the study of biologically relevant molecules in the interstellar medium and in primitive solar system objects such as comets, undifferentiated asteroids, and some meteorites; the search for intelligent signals of extraterrestrial origin (► [SETI](#)); and the study of the origin, early evolution, and environmental conditions for life on Earth. The coordination of efforts in all these areas at the international level and the establishment of collaborative programs with other international scientific societies with related interests are among the duties of this IAU Commission.

History

The International Astronomical Union established the Commission 51, “Bioastronomy: Search for

Extraterrestrial Life,” in 1982. The Commission was renamed simply “Bioastronomy” in 2006 and renamed again “Astrobiology” in 2015, when it was also renumbered as Commission F3. From an early concentration on ► [SETI](#), the Astrobiology Commission has expanded its interests as described in the previous paragraph. In most current usage, bioastronomy and astrobiology are synonyms.

 Philosophy of science · Science ·
 Multidisciplinary

Definition

“Astrobiology as science” refers to how astrobiology is characterized and discussed in the philosophy of science.

Overview

The name “astrobiology” could be interpreted to imply that astrobiological research is limited to the search for, and eventual study of, extraterrestrial life (as was the case with astrobiology’s predecessor, exobiology). This interpretation of the term “astrobiology” would be misleading, however. “Astrobiology” is commonly defined as “the study of the origin, evolution, distribution, and future of life in the universe” (e.g.,

Blumberg 2011; Dunér et al. 2018). In the latest edition of the *Astrobiology Primer* (Domagal-Goldman and Katherine 2016), “astrobiology” is defined as “the science that seeks to understand the story of life in our universe.” Both these definitions, as well as a look at the research published in journals and presented at conferences dedicated to astrobiology, tells us that the focus of astrobiology is rather on the universal aspects of biology. If biology primarily studies living organisms, relations between living organisms, and relations between living organisms and their environments, it can be said that the focus of astrobiology is on the phenomenon of life as such, including eventual universal properties of life, its boundaries, and its boundary conditions. This means, for instance, that though many astrobiologists do study organisms in the form of extremophiles and the relation between these organisms and their environments, astrobiologists are not (in their role as astrobiologists) focused on the particular organism they study, but on properties that can inform our understanding of life as a phenomenon, general properties of life and life’s boundaries and boundary conditions.

Taxonomy

Whether astrobiology should count as a discipline, a research field, or something else entirely, is a matter of ongoing discussion (Dick 2020; Michaud 2007). Astrobiology does fulfill some commonly accepted criteria for being a discipline, such as having its own questions and its own journals, conferences, and professional societies. A number of universities have centers that focus entirely or partly on astrobiology, though it is still uncommon for universities to have astrobiology departments. An increasing number of universities also offer courses and programs in astrobiology. On the other hand, there is no particular astrobiological method. Instead, astrobiology uses a multitude of methods borrowed from (other) disciplines. It has therefore been suggested that astrobiology is best characterized as an interdisciplinary (e.g., Grinspoon 2003; International Journal of Astrobiology 2002; Michaud 2007) or

multidisciplinary (e.g., Dick and Strick 2004) science. It has also been referred to as a meta-discipline by Grinspoon (2003) and Michaud (2007).

Czyżewska (2013) uses both “multidisciplinary” and “interdisciplinary” when talking about astrobiology, which may in fact be the most correct way to characterize astrobiology. Many studies in astrobiology are performed strictly within the borders of a traditional discipline, but it takes many such studies from different disciplines to answer some of the questions of astrobiology. In this sense, astrobiology is multidisciplinary. On the other hand, some of astrobiology’s questions call for genuinely interdisciplinary studies. It is also often insufficient to just add together results from different disciplines to answer the bigger questions of astrobiology. Instead, the work of synthesizing results from different intra- and interdisciplinary studies into answers to astrobiological questions needs to be interdisciplinary in itself. So, astrobiology is also interdisciplinary.

The term “metadiscipline” used by Grinspoon (2003) and Michaud (2007) is less well established and defined than the terms “multidisciplinary” and “interdisciplinary.” Michaud (2007) uses the term to emphasize astrobiology’s ambition to formulate universal laws and a universal theory of biology. This ambition is echoed by Blumberg (2011), though without using the term “metadiscipline.” Grinspoon (2003) uses the term in connection with describing astrobiology as being “potentially revolutionary in its attempt to reverse the slide toward increasing scientific specialization and isolation,” adding a will to “blur the borders and tear down the walls that modern academia has erected.” Lynn Rothschild reasoned along the same lines by declaring that astrobiology “liberates us from disciplinary boundaries” (Dick and Strick 2004).

If it is correct to say that astrobiology, in addition to its explicit research goals, also has the ambition to transform (another) discipline and/or to transcend or abolish the borders of (other) disciplines, it may make sense to describe astrobiology as metadisciplinary, in addition to being multi- and interdisciplinary.

Is Astrobiology a Science Without a Subject?

In 1964, biologist George Gaylord Simpson criticized exobiology for being a science that has yet to show that its subject matter exists (Simpson 1964). From a philosophy of science perspective, Simpson's critique was misinformed since the aim of exobiology was not merely to study extraterrestrial life but also, and primarily, to find it – an aim that is perfectly consistent with extraterrestrial life not yet having been found or shown to exist. Looking for something that is not yet known for sure to exist is in fact, not an unusual scientific aim. It is an aim that exobiology has in common with, for instance, the search for the Higgs Boson, the search for exoplanets (Dick 2020), the search for black holes, and the search for Neptune and Pluto, all of which have now succeeded. Simpson's words are sometimes also used about astrobiology where they are misguided for the same reason, but also because the scope of astrobiology is different from that of exobiology through astrobiology's focus on life as a phenomenon, where finding and studying extraterrestrial life would be important milestones but not the only or the ultimate goals.

Astrobiology as an Empirical Science

Even though the characterization of astrobiology as a science without a subject is incorrect, the fact that we so far only have one example of life (namely Earth life), means the empirical basis for astrobiology is still relatively weak. This is presently handled in two ways. One is to continue to collect data about the life we know on Earth, as well as about its living conditions on Earth and the physical and chemical conditions on other worlds. The other is to continue searching for a second data point (that is, extraterrestrial life).

Given, however, that we will (presumably) never be able to find every life-form in the universe or travel in time, the main aim of astrobiology cannot be to find the ultimate truth about how life actually started on Earth or in the universe, exactly how life is distributed in the universe, or

be absolutely certain that the laws and theories we formulate about life are truly universal. On the other hand, this does not mean in any way that the field is completely open for speculation. The space for speculation is circumscribed by logic and mathematics, but also by existing data. As an empirical science, astrobiology also moves forward by continuing to formulate explanations that are possible given the current state of knowledge, while at the same time keep narrowing down the number of possible explanations by formulating testable hypotheses and figuring out new and better ways of testing these hypotheses. Through this general method, the room for speculation will successively shrink.

SETI

Another controversy regards whether the search for extraterrestrial intelligence (SETI) is a proper part of astrobiology (Almár and Race 2011). This controversy is not in a strict sense a matter of philosophy of science, however, but rather a matter of the politics and sociology of science (Dick and Strick 2004; Michaud 2007). From a strictly scientific and philosophy of science perspective, neither the scientific status of SETI, nor its fit within the broader area of astrobiology can be considered controversial.

Astrometric Orbit

David W. Latham¹ and Nader Haghighipour²
¹Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA
²Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, Hawaii, HI, USA

Definition

When two bodies are in ► [Keplerian orbits](#) around a common center of mass, the apparent motion projected onto the plane of the sky defines an astrometric orbit. In some cases, such as the famous example of Sirius A and its white dwarf companion Sirius B, both objects can be spatially resolved, and their absolute positions and motions can be determined. This allows the ratio of the two masses to be determined, which can be combined with the total mass, if the distance is known, to derive individual masses. More often, only a single photocenter can be resolved, and only motions relative to nearby stars can be determined. In this

case an orbital solution requires additional information about the relative brightness of the components. In the case of a planetary companion, the contribution of the planet to the total light can almost always be neglected, and the mass of the planet can be estimated from the observed wobble of the parent star if the mass of the star and its distance can be estimated. In common with a spectroscopic orbit determined from radial velocities along the line of sight, an astrometric orbit also yields the ► [period](#), ► [eccentricity](#), and time of ► [periastron](#) passage. Astrometry has the advantage over radial velocity of measuring motions in two dimensions on the plane of the sky instead of just one motion along the line of sight, and this allows the orbital inclination to be determined. Thus, astrometric orbits can eliminate the ambiguity of the unknown orbital inclination and can yield actual masses under certain circumstances, for example, when applied to minimum masses determined by spectroscopic orbits.

Astrometry · Coplanar orbits · Orbital inclination · Perturbation · Planetary mass · *HST* FGS

Definition

Astrometry is a discipline of astronomy that is concerned with the measurements of stellar positions. As applied to exoplanets, a series of astrometric measurements over time is analyzed to obtain an estimate of the size of the reflex motion of the host star caused by the gravitational pull of its unseen planet. The planet and its host star orbit a common center of mass. Given an estimate of the mass of the host star, normally from the mass-luminosity relation, one can determine the mass of the planet. Astrometry also provides the orbital inclination of exoplanets. The knowledge of the orbital inclination of a planet will enable us to determine the true value of its mass (see “► [Inclination \(Astronomy\)](#)”) and can also be used to constrain models of planet formation.

History

The history of astrometric planets is littered with past failures. A notable example was the reported discovery of a planetary system associated with Barnard’s star by van de Kamp (1969), which was subsequently disproven through reanalysis of the data by Ianna (1995) and re-observation of the same system by Benedict et al. (1999). Astrometry has yet to *discover* an independently verified exoplanet; although as a technique to further characterize the companions to stars discovered by precision Doppler measurements (radial velocities), it has enjoyed some recent successes. Future successes (both discovery and characterization) are expected from the astrometric satellite Gaia.

Overview

We describe some of the astrometric planet results obtained using one of the Fine Guidance Sensors (FGS) aboard the *Hubble Space Telescope* (*HST*). The techniques employed are illustrative of both past astrometric approaches and future astrometric investigations. Exoplanetary

astrometry relates the time-varying position of a target to positions of stars defining a reference frame. To obtain the orbital elements of the perturbation due to the companion, one must first characterize motions extrinsic to the system: parallax and proper motion (defined below). Anyone attempting to measure a perturbation will find (to either their delight or horror) that the Earth orbits the ► [barycenter](#) of the Solar System. The corresponding apparent motion of the host star evidences itself as an ellipse, which for nearby stars can exceed 100 milli-arcsec (mas) in size. Added to that parallactic motion is the apparent motion of the host star across the line of sight due to the transverse component of the star's space velocity relative to our Sun. This proper motion often exceeds 50 mas/year. We use the determination of the mass of the planetary companion HD 38529 c (Benedict et al. 2010) as an example of the methodology. The star HD 38529 (= HIP 27253 = HR 1988 = PLX 1320) hosts two known companions b and c, discovered by high-precision ► [radial velocity](#) (RV) monitoring (see Wright et al. 2009). Previously published minimum masses of HD 38529b and c were 0.85 and 13.1 Jupiter masses, respectively. The latter lies just above the official definition of the transition between planets and brown dwarfs. A predicted minimum perturbation of the semimajor axis = 0.8 mas for the outermost companion, HD 38529 c, motivated us to obtain astrometric observations with mas precision using *HST* FGS, to determine the

orbital inclination and thus the true mass of this planet. These astrometric data span 3.25 years of the complete 5.85-year period.

Basic Methodology

Our approach depends on the discovery and orbital characterization results from radial velocity studies. Specifically, the period, eccentricity, time of periastron passage, and position angle of periastron (P, e, T, ω) of the perturbing body are initially known. As can be seen from Table 1, most of our target systems have periods far in excess of 2 years. The data from the astrometry and radial velocity are combined through the constraint (Pourbaix and Jorissen 2000), $\alpha \sin i / \pi_{\text{abs}} = P K (1 - e^2)^{1/2} / (2\pi \times 4.7405)$, where quantities derived only from astrometry (parallax, π_{abs} ; apparent semimajor axis of the elliptical perturbation, α ; and inclination, i) appear on the left, and quantities derivable from both the period P and eccentricity e , or from radial velocity only (the RV amplitude of the primary K), appear on the right. In most cases such as the one here, given the fractional orbital coverage of the HD 38529 c perturbation afforded by the astrometry, all the quantities on the right-hand side are dominated by the radial velocities (Table 1).

Before analysis, all astrometric measurements from the FGS are corrected for optical field angle distortion. Like the part of an iceberg below the

Astrometric Planets, Table 1 *HST* FGS astrometric results. Fe/H measures the abundance of iron relative to hydrogen on a logarithmic scale normalized to the Sun. Sp.T. is the spectral type of the host star

Companion	M_* ($M_{\odot}$)	[Fe/H]	Sp.T.	d(pc)	ecc	M (M_{Jup})	α (mas)	Inc ($^{\circ}$)	P(d)

HD 128311 C	0.84	0.02	K0 V	16.5	0.16	3.8 ± 0.7	0.46	56 ± 14	921.5d

water, this correction, while typically “out of sight” (McArthur et al. 2003), is an essential part of our process. Actual FGS distortions with amplitudes in excess of 1 arcsec are reduced to 1 mas or less over the FGS field of regard.

We are able to relate the position of the bright host star to the far fainter reference frame stars through the use of a neutral density filter. The astrometric reference frame for HD 38529 consists of four stars. Any prior knowledge concerning these four stars eventually enters our modeling as observations with errors, which helps improve the values of the parallax and proper motion for the prime target, HD 38529. Distances to the reference stars are estimated from (BVIJHK) photometry and stellar classification spectroscopy. Of particular value are independently measured proper motions from the UCAC3 catalog (Zacharias et al. 2010). All these periodic and nonperiodic motions must be removed as accurately and precisely as possible to obtain the orbital inclination, i , and perturbation size, α , caused by HD 38529 c.

Key Research Findings

Results from *HST* astrometry are presented in the table above. HD 38529 c is clearly more massive than 13 Jupiter masses, the threshold above which deuterium fuses to helium. This threshold has been adopted by the International Astronomical Union as the official transition between planets and brown dwarfs.

Other results: McArthur et al. (2010) determined the inclinations of components c and d in the ν Andromeda system, indicating non-coplanarity. Whether this architecture is a result of the migration of component b (with $M_{\text{sin}i} = 0.69 M_{\text{Jup}}$) now in a $P = 4.6$ -day orbit, or the past passage of the M star companion, ν Andromeda B, is as yet unknown (Barnes et al. 2011). A recent attempt to determine the degree of coplanarity for HD 128311 was unsuccessful, but did yield a planetary mass for component c (McArthur et al. 2014). A review of the results

made with HST can be found in Benedict et al. (2017).

Applications

These techniques have been applied to determine masses for 14 Her b, HD 47536 b, and HD 168443 c. There now exist sufficient FGS astrometric measurements to attempt to determine orbital inclinations for b and c, HD 202206 b and c, μ Ara b and c, and γ Cep A and b. The latter two host stars may be too bright for Gaia. If the degree of orbital coplanarity can be established for those systems, astronomers will have valuable data to probe the architectural uniqueness (or not) of our own Solar System, complementing analogous results from the recent Kepler transit discoveries and the study of ► [radial velocity planets](#).

Note that other instruments have also contributed to achieving astrometric constraints of the masses and inclinations of the planets of various systems, like VLT/SPHERE (e.g., for the system HR8799, Wertz et al. 2017) and the interferometric instrument VLTI/GRAVITY (e.g., for the system β Pictoris b, Gravity Collaboration et al. 2020).

Future Directions

Major progress will result from two improvements to past practice as exemplified by *HST* FGS astrometry. First, future missions will employ global (as opposed to local) reference frames, removing the correction to absolute parallax required when using a local reference frame. Second, the astrometric precision will improve by two orders of magnitude, from millisecond of arc to micro-arcseconds (μas). Future success is expected from *Gaia*, an astrometric satellite launched on December 2013 by the ► [European Space Agency \(ESA\)](#). The expected 10 μas mission accuracy

should permit the discovery of 21,000 massive planets (mass higher than Jupiter's) on long-period orbits (Perryman et al. 2014). This number can go as high as 70,000 if the nominal 5-year mission is extended to 10 years. However, the unambiguous astrometric identification of an Earth-mass exoplanet, orbiting a nearby Sunlike star at a star-planet separation allowing surface liquid water, remains a difficult goal, one requiring 1 μ as/observation precision.

Definition

Astrometry is that part of astronomy dealing with the determination of the position, distance, and motion of celestial bodies and by extension their size and shape. This is by far the oldest branch of astronomy, and until the mid-1800s, the word did not even exist. It was only coined at that time to make the distinction from the new field of astrophysics.

Overview

Taken as a broad subject, *astrometry* covers the definition and realization of the astronomical ► [coordinate systems](#) and the construction and maintenance of positional star catalogues, but also the techniques for the computation of astronomical events, like eclipses, passages of inner planets across the Sun's disk, orbits of ► [binary stars](#), stellar ► [occultation](#) by the Moon, or the minor planets. Classical astrometry is undergoing a true revolution with the access to radio interferometry and above all the possibility to carry out accurate measurements from space, thanks to the Hipparcos mission (1989–1996) and the ongoing Gaia mission (launched in

2013 and expected to continue operations to 2025). The main benefit of doing astrometry in space is the measurement of absolute parallaxes of stars, that is to say their distances, just from the geometric method without any assumptions on the physics of the sources or on the absorption of the light during its journey to the telescope.

Given the fundamental nature of its investigations, it is fair to state that astrometric data, leading to the realization of an accessible ► [reference frame](#) or giving the distances and the masses of the stars, provide the foundation of stellar physics and of the cosmic distance ladder. Stellar distances are the key to determining stellar luminosities and then for calibrating further methods to determine distances up to the most remote galaxies.

Based on the tools employed and on the objectives, astrometry can be further divided up into three broad categories:

- Small-angle astrometry, measuring the position or the motion of stars in a very small field (less than 1°) with respect to local references. This was typical of astronomical photography until the advent of charged coupled device (► [CCDs](#)) and is still used for solar system astrometry or to determine the relative motion within a binary system. Its accuracy can reach 1 mas (0.001 arc sec) in relative positions.
- Wide-angle astrometry was the basis for the construction of the fundamental catalogues and their extension to fainter magnitudes. The classical instruments were the meridian circles and the astrolabes. Stars over the whole celestial sphere were tied together, thanks to the rotation of the Earth or by overlapping frames in photographic or ► [CCD](#) astrometry. The accuracy, including zonal errors, is of the order of 20 mas for the bright stars (visual ► [magnitude](#) $V < 8$) and 50–70 mas at around $V = 15$.
- Space astrometry is the only way to do absolute measurements over the whole sky with a single instrument able to connect widely separated directions ($>60^\circ$) and perform repeated observations over several years. This method leads to an absolute catalogue of positions and

► [proper motions](#), independent of any pre-existing reference frame. Accuracy was 1 mas with ► [Hipparcos](#) (~120,000 sources) and has already reached 0.025 mas at $V = 15$ in the early releases of ► [Gaia](#) which delivers accurate position, parallaxes, and proper motions for nearly two billion sources. Radio ► [interferometry](#) and Gaia perform absolute astrometry of quasars on the whole celestial sphere, respectively in the radio and visible domain of wavelengths. The associated catalogues are currently the basis of the astronomical reference frame (ICRF: International Celestial Reference Frame) with a similar accuracy of about 0.1 mas over a few thousands radio sources in the radio domain and about 500,000 in the visible domain. The solutions are so constructed to have the same fundamental plane and the same origin of right ascension in this plane, by using sources observed by both techniques.

Asymmetric Reaction, Absolute

Kazumichi Nakagawa
Sanken, Osaka University, Ibaraki City, Osaka, Japan

Keywords

Asymmetric decomposition · Asymmetric synthesis · Circularly polarized light · Origin of homochirality · Induction of chirality

Definition

An absolute asymmetric chemical reaction is one induced by asymmetric physical conditions such as circularly polarized light (CPL) instead of by chemical reagents or catalysts. They can be divided into two categories: One is asymmetric synthesis, and the other is asymmetric decomposition.

Overview

Asymmetric synthesis is driven by the introduction of chirality into an achiral system, a process

known as asymmetric induction. One example of absolute asymmetric synthesis is the introduction of optical activity into helicenes (twisted polycyclic aromatic hydrocarbons with six rings) studied by Kagan et al. (1974) in 1971, in which the optical yield was lower than 1%. Enantiomeric enrichment of racemic compound such as amino acids by irradiation with circularly polarized light (CPL) is one of the well-known examples of asymmetric decomposition. The first experimental evidence of CPL-induced asymmetric decomposition was reported by Kuhn and Knopf (1930).

Various light sources such as lasers and synchrotron radiation are now available as powerful tools to study asymmetric reactions. Several studies have examined the role of asymmetric reactions on the origin of ► [homochirality](#) in biological molecules: Flores et al. (1977), Nishino et al. (2001), and Meierhenrich et al. (2005).

Polarized radiation from pulsars and interstellar masers has been known for several decades. Natural sources of circularly polarized light were found in space and reported by Bailey et al. (1998). Mie scattering and synchrotron radiation are thought to be the natural sources of circularly polarized light.

Other mechanisms of absolute asymmetric reactions have been discussed by Bonner et al. (1974), Bonner (2000), and Goldanskii and Kuzmin (1989).

Atacama Desert

Richard Léveillé
Natural Resource Sciences, McGill University,
St. Anne de Bellevue, QC, Canada

Definition

The Atacama is a hyperarid desert located in northern Chile. It is considered to be one of the driest places on Earth with average annual rainfall of less than 1 mm in some locations. It is a useful analogue to the arid surface of Mars and for analog studies of hydrology, mineralogy, and microbiology. Features that may be analogous to Mars also include caves, salt deposits, water-derived mudflows, and gully-type deposits. Field tests of prototype instruments and rovers have also been conducted there.

Atacama Desert, Natural Analog

Daniele L. Pinti
GEOTOP Research Center for the Dynamics of
the Earth System, Université du Québec à
Montréal, QC, Canada

Definition

The ► [Atacama Desert](#) is a desert plateau situated along the western coast of South America, west of the Andes, and occupying a surface of 104,741 km². The Atacama Desert is the driest nonpolar desert on Earth, only the Antarctica dry valleys are drier, even if the Atacama receives fewer annual precipitations (maximum 39 mm per year) than the polar deserts (average of 250 mm per year). The Atacama Desert has been extensively used as experimentation site for Mars expedition simulations and as natural analog of the Red Planet past climatic and geological conditions. Morphological aspects of the desertic terrains and the presence of large alluvial fans were compared with those of Mars to understand their conditions of formation. Finally, the extreme conditions of survival of microbial (mainly extremophiles) communities have been also studied to determine the habitability threshold which could be found on other arid planetary surfaces.

Overview

The Atacama Desert owes its extreme aridity to a constant temperature inversion (the warmer humid air is maintained above a cooler drier air mass) caused by the encounter between the Humboldt oceanic current (a cold, low-salinity ocean current that flows north along the western coast of South America) and by the presence of the semi-

permanent Pacific anticyclone, which creates an area of constant high atmospheric pressure. The Atacama Desert is composed mainly of stony terrain, salt lakes (*salares* such as the *Salar of Atacama*, owing one of the more important Lithium reserves on Earth), sand, and felsic lava flowing from the Andean volcanoes.

In the last three decades, the Atacama Desert has been used for testing exploration rovers (e.g., Cabrol et al. 2001) and life detection systems (Good 2017); numerous geological and morphological aspects of the terrains were studied and compared to those found on Mars to understand their formation (e.g., Levy et al. 2010; Morgan et al. 2014; Sager et al. 2021); and finally subsurface microbial habitats investigated to determine minimal environmental conditions to support life in arid conditions, such as those of Mars subsoil (e.g., Azua-Bustos et al. 2020).

Between June and July 1997, 3 months after the arrival of the first-ever rover on Mars (Mars Pathfinder, March 1997), Carnegie Mellon University deployed the robotic rover Nomad to traverse the Atacama Desert (Cabrol et al. 2001). Nomad traveled an unprecedented 215 km in 45 days, and it was remotely driven from the Ames research center and the Carnegie Science Center in Pittsburgh, PA. The Atacama trek of the Nomad rover allowed to test technologies critical to planetary exploration such as remote communication systems and the use of panospheric 360° view camera, which was the ancestor of the more sophisticated 360° cameras now embarked on Mars rovers. The robot also had three pairs of conventional stereo cameras and a laser telemeter for 3D visualization. Among the most important lessons learned from the Nomad trek through the Atacama Desert was that the selection of appropriate targets could even more critical than the time spent in an area, to reconstruct the history of the selected site (Cabrol et al. 2001). Devices for detection of life forms were also tested such as the NASA-funded *Chemical Laptop*, a subcritical water extractor able to analyze water bounded in minerals to detect the presence of amino acids (Good 2017) and which could be used to search for biosignatures in solid samples on rocky or icy worlds.

Several geological and morphological features found on Mars have their equivalent in the Atacama Desert. Among them, the presence of polygonal grounds in salt-cemented soils of the Yungai area (Sager et al. 2021) which resemble to polygonal surfaces found in the northern and southern hemisphere of Mars, between 30° and 80° latitude (Levy et al. 2010). On Earth polygonal grounds are landscape features commonly associated with periglacial environments originating from freeze-thawing cycles or frost-related processes. However, such a mechanism cannot be applied to the hyperarid Atacama Desert. Conclusions of Sager et al. (2021) study is that cyclic thermal contraction cracking is the dominant formation mechanism rather than desiccation cracking, though presence of gypsum salt cannot exclude a minor role of desiccation. This mechanism is likely the one dominating on Mars, where arid climate and salt surface are present (Levy et al. 2010; Sager et al. 2021).

Alluvial fans in arid climates are another common geological feature of Mars and the Atacama Desert. Alluvial fans are sedimentary landforms formed at the base of mountain fronts where a fluvial channel emerges onto a valley floor, and the drastic reduction in the slope forces the deposition of large amounts of sediments. The presence of alluvial fans on Earth is an index of presence of water (fluvial activity) and run-off. On Mars, large alluvial fans offer compelling evidence that surface runoff persisted, at least episodically, into the Hesperian or Amazonian periods (Moore and Howard 2005). This era has generally been thought to be cold and dry, and characterizing the climatic environment that permitted the formation of those fans can give clues into past Mars potential habitability (Morgan et al. 2014). The Martian and Atacama Desert alluvial fans share numerous similarities: they are very large (up to 200 km² in the Atacama); gently sloped (5°); dominantly fine-grained composition; with reworking of inactive fan surfaces by aeolian processes. For both, the dominant flow regime is bimodal, with channels transporting cobble- to boulder-size bedload and fine-grained mudflows that extend laterally from the channel (Morgan et al. 2014). Thus, the study of formation

mechanisms of large alluvial fans on the front of Andes in the Atacama Desert might give clues on the amount of water and climatic conditions of past Mars.

Finally, the presence of microbial communities in the arid soils of the Atacama Desert, where humidity is generally close to zero, has amazed biologists and pushed the scientific community to study the environmental condition of survival of those communities, which could give clues on habitability threshold in similar arid planetary surfaces (Navarro-González et al. 2003). Several microbial communities are halophilic Archaea living in the salt-enriched arid soils of Atacama. Very recently, Azua-Bustos et al. (2020) have discovered a layer of smectite (a clay mineral formed by water-rock interactions) just 30 cm below the arid soils of the Yungai region. This smectite creates a micro-environment completely isolated from the surface, maintaining an exceptionally high degree of humidity for the region (78%), where at least 30 ► [halophile](#) species of metabolically active bacteria and archaea live. The discovery of microbial communities in those smectite-rich subsurface layers of the Atacama soils suggest that similar shallow clay deposits on Mars may contain biosignatures easily reachable by future rovers, such as in 2023 by the ESA's *Rosalind Franklin* rover which will land in the smectite-rich surfaces of *Oxia Planum*.

Definition

It is widely thought that the origin of life on a planet may depend on the availability of abiotically synthesized organic compounds. Various potential sources for these exist, including extraterrestrial delivery and submarine hydrothermal synthesis. However, one of the first suggested means of producing these compounds was via synthesis in the gas phase in planetary atmospheres, as shown by the results of the now famous experiment published by Stanley Miller in 1953. It has now been amply demonstrated that the action of various forms of energy, including shock waves, electricity, and

ionizing and UV radiation acting on various simulated planetary atmospheres can result in the synthesis of a variety of organic compounds. In general, more reduced gas mixture atmospheres appear to give more favorable yields of organic compounds; however, even relatively oxidized gas mixtures still produce organics to some extent.

Definition

An atmosphere (or an atmospheric envelope) typically refers to the gas that is gravitationally bound to a planet or another planetary object. In relation to planet formation, atmospheres composed of hydrogen and helium are thought to form as a result of gas accretion by a growing planet embedded in a ► [protoplanetary disk](#). For low-mass planets or even Moon- to Mars-sized planetary embryos, a relatively small amount of gas may be gravitationally captured into a primitive atmosphere. The atmospheres of full-size terrestrial planets are then made up of a combination of atmospheres from their constituent planetary embryos, as well as volatiles that may be degassed from the planetary interior or delivered to the planet via impacts of

small bodies during final stages of accretion (► [late veneer](#)). In that case a large range of atmospheric compositions is possible, and the atmospheres can consist of water and other volatile materials.

Definition

Atmospheric structure usually refers to changes in physical quantities such as temperature, density, etc., in the vertical. Atmospheres can be classified into regions (troposphere, stratosphere, mesosphere, etc.) depending upon the variation of temperature and physical processes in the vertical.

Overview

The vertical structure of an atmosphere is mostly controlled by gravity on one side, and stellar energy absorption on the other side. Gravity controls this vertical structure through the hydrostatic equilibrium, that states that the weight of one given gas element is balanced by the vertical pressure gradient. According to the corresponding equation, pressure is decreasing quasi-exponentially when altitude increases. The scale height, corresponding to a decrease of pressure of a factor e , depends on temperature, and therefore varies with altitude.

A first level of structure in a given atmosphere is related to the atmospheric composition. When pressure is high enough, eddy diffusion is the dominant mixing process and atmospheric composition is uniform (at least with the dominant atmospheric components). This region is called the “homosphere.” When pressure decreases and molecular diffusion becomes dominant over eddy diffusion, each dominant constituent follows its own atmospheric scale height and lighter constituents separate from heavier, with the mean molecular weight varying with altitude. This region is the “heterosphere.” The limit between homosphere and heterosphere is called the “homopause” (on Earth, it is located around 90 km of altitude). The heterosphere is limited at its top by the “exobase,” where the atmospheric scale height equals the molecular mean free path. Above this transition, it is the “exosphere” – the uppermost atmosphere region before space. The top of the exosphere can be defined to occur where the stellar pressure equals the planetary gravitational pull on a hydrogen atom.

In terms of temperature structure, the atmosphere is organized in layers, depending on the energy transfer and balance mechanisms. Energy sources are the solar (or stellar) input flux, and in some cases an internal energy flux (radioactive decay or gravitational contraction). The energy

balance is also controlled by the way the absorbed stellar energy is reemitted in the infrared toward space.

In lower regions, with stellar energy absorbed by the surface or internal energy flux, convection is important. Warm air lies below cool air and vertical mixing is strong – this is the “troposphere” region, which is characterized by a decrease of temperature with altitude, up to the “tropopause” (Fig. 1). In the troposphere, since energy transfer is dominated by convection, the average temperature gradient is close to the adiabatic lapse rate, that can be dry, or moist when latent heat exchanges are involved during convective motions. Near pressures lower than about 0.1 bar (on Earth, Jupiter, Uranus) radiative transfer starts to dominate over convection. On Earth, the tropopause is located around 12 km altitude.

At higher altitudes, temperature may increase with altitude due to absorption of some of the incoming UV energy. This is the case on Earth with UV absorption by ozone. Cool air lies below warm air and vertical mixing is weak – this is the “stratosphere” region, a highly stable, stratified region where temperature increases with altitude. The energy transfer is done through radiation, and this radiative equilibrium is controlled, at each level, by the opacity sources and the

Atmosphere, Structure,

Fig. 1 Temperature structure of Earth, Jupiter, and Uranus, showing the presence in similar pressure ranges of a troposphere, a stratosphere, and a mesosphere

balance between the total energy absorbed, and the energy reemitted in infrared. It is strongly dependent on the spectroscopic properties of the atmospheric constituents. Above the maximum of temperature named the “stratopause,” temperature decreases again with altitude in a region called the “mesosphere.” On Earth, the stratopause is located around 50 km altitude, where ozone concentrations are small. Depending on the atmospheric composition, on the presence of haze or clouds, a stratosphere is not always present. As an example, Venus or Mars, both CO₂-dominated atmospheres, do not have a stratosphere. On Venus, the tropopause region is located in the upper cloud, and despite the strong UV absorption in this region, infrared cooling is also large and the region stays roughly isothermal. Above the clouds, infrared cooling dominates and the radiative balance leads to temperature decreasing again with altitude, transitioning directly from troposphere to mesosphere. On Mars, the tropopause merges in a roughly isothermal mesosphere.

In the stratosphere and mesosphere, local thermodynamic equilibrium (LTE) is valid. This means that at every frequency, a given atmospheric level with temperature T emits as a black body. But when pressure decreases again, after reaching a minimum (“mesopause”), temperature rises again with altitude due to the absorption of high energy radiation. This is the “thermosphere,” where non-LTE processes need to be taken into account. Thermosphere reaches up to the exobase. Though not defined on the same physical criteria, thermosphere and heterosphere are approximately overlapping.

Finally, another layer usually overlaps with the thermosphere: the ionosphere, a region where ions and electrons are present, due to photoionization of molecules and atoms.

Atmosphere, Temperature Inversion

Lisa Kaltenegger

Cornell University, Ithaca, NY, USA

Keywords

Atmosphere structure · Biomarkers · Habitability · Habitable zone · Temperature inversion

Definition

A temperature inversion refers to a reversal in the normal decrease of atmospheric temperature with altitude in the lower portion (▶ [troposphere](#)) of a planetary atmosphere (atmosphere, Structure). Temperature inversions inhibit vertical motion, because the warmer, less dense air is at a higher altitude and tends to remain there. The net result of a temperature inversion is a long time constant for exchange between a stratosphere and a troposphere. It exists due to the heating produced by absorption of sunlight by molecules or aerosols that are chemically produced. There exists a highly non-linear positive feedback between chemistry, radiation, and dynamics, such that absorbers will remain longer, hence lead to a larger thermal inversion, resulting in the trapping of even more absorbers (Pierrehumbert 2011).

Overview

In the troposphere, convection dominates and the temperature decreases according to the so-called wet lapse rate, about 6.5 K/km for Earth (which includes the latent heat released by the condensation of water). Mixing is generally rapid in a troposphere, as the warm, lighter air at the bottom tends to rise and the colder air at the top tends to sink down. The thermal inversion in the stratosphere on Earth is due to absorption of ultraviolet radiation by Ozone (O₃) but can be generated by other molecules on different planets. Above Earth's stratosphere where O₃ is no longer strongly produced, the temperature decreases with height due to cooling in the infrared, mainly by CO₂. In the outermost atmosphere, Earth's hot thermosphere is related to absorption of extreme ultraviolet radiation by O₂, N₂, and O.

In contrast to the Earth, Mars has a thin and Venus a thick atmosphere, which is reflected in their surface temperatures. The tropospheric temperatures of Mars and Venus follow their respective lapse rates (atmospheric thermal gradient). There are no well defined stratospheric inversions, except during dust storms on Mars. The thermospheres of both planets are relatively cold compared to Earth's, because the major atmospheric gas (CO₂) is a very effective radiator of thermal energy. In contrast, the primarily apolar constituents of Earth's atmosphere (N₂, O₂) have virtually no bands in the infrared and are poor radiators.

Definition

The atmospheric circulation is the study of the global, large-scale motions, averaged over a time period, of the atmospheres surrounding the planets and satellites.

Overview

The atmospheric circulation is the study of the global, large-scale motions, averaged over a certain periods of time, of the gases (atmospheres) surrounding planets and satellites. The mass motions are represented by three components of

the velocity on the sphere or ellipsoid that represents the planet figure, relative to planet rotation reference frame. Spatial and temporal averages of the winds show the global trends of the general circulation of the atmosphere. Other ways of representing the atmospheric circulation are by means of the mass stream-function (in particular when referring to meridional motions) and the temperature field (because of its relationship to velocity).

The comparative study of planetary atmospheres shows that their circulation is determined by the energy sources, the rotation angular velocity, the size of the planet, and its structure (presence of a solid surface or fluid planet). The energy sources can be the solar radiation deposited in the atmosphere that produces spatially and temporally variable heating and cooling rates, and the internal energy source important on giant and icy planets. The planetary rotation varies widely from days to few hours in solar system bodies and is the key parameter in shaping the atmospheric motions. According to their structure, the planets are divided in two large groups, on one hand the terrestrial or telluric type, with small size and a solid surface as the lower boundary to the atmospheric motions (Venus, Earth, Mars, and Saturn’s satellite Titan). On the other hand, the giant gaseous (Jupiter and Saturn) and the intermediate size ice giants (Uranus and Neptune) all them with deep atmospheres and no solid surface. Accordingly, the comparative view of the atmospheric circulations of the planets can be grouped in the following couples: slowly rotating

terrestrial bodies (Venus and Titan), rapidly rotating terrestrial planets (Earth and Mars), the gas giants (Jupiter and Saturn) and the icy giants (Uranus and Neptune).

Venus and Titan

Venus is the planet with the longest rotation period in the solar system (Table 1). However, its atmosphere is in a state of superrotation at cloud level (at an altitude from the surface between 40 and 65 km) and exhibits a period in the range 4–6 days. The atmospheric circulation is dominated by prograde zonal motions (i.e., in the direction of rotation of the planet) which given the high inclination of the rotation axis of the planet are from East to West. The zonal wind velocity (u) has practically a constant value in the range -100 to -110 ms^{-1} at cloud tops at 65 km of altitude and in a wide range of latitudes from 50°N to 50°S (Fig. 1a). This zonal velocity decreases towards the poles where forms two large polar cyclones that have rotation periods of 2–3 days. This zonal wind system has a large vertical shear with velocity decreasing with altitude at a rate of $\partial u/\partial z = 1.5\text{ ms}^{-1}/\text{km}$ from cloud tops to the surface (Fig. 1b). At the surface, the speed is practically zero in the 10 km above the surface. Meridional winds (across latitudes) have been measured at an altitude of 65 km with peak velocities of 15 ms^{-1} probably related to a Hadley circulation. Vertical motions with speeds fluctuating between 1 and 3 ms^{-1} were measured at 50–55 km altitude by the Vega balloons. Superimposed to the prevailing zonal flow coexist a variety of waves with

Atmospheric Circulation, Fig. 1 Wind profiles in Venus and Titan: (a) Venus zonal wind as a function of latitude as measured at the upper cloud level at an altitude of 65–70 km above the surface. Averaged wind values from the following missions: Mariner 10, 1974 (black dashed); Pioneer-Venus, 1980 (blue dotted); Pioneer-Venus, 1982 (red dotted); Galileo, 1990 (brown line); Venus Express VIRTIS, 2006–2012 (black line); Venus Express VMC, 2006–2012 (green line). (b) Venus vertical zonal wind profile measured at different latitudes and local times. Continuous lines as measured by four Pioneer-

Venus probes (1978): Sounder (green), North (black), Night (red), and Day (blue). The green dot is the velocity measured by the Vega 1 and 2 balloons (1985) at latitudes (+7.3°, −6.6°) and sounded day and night time. The rectangles are mean values from long-term measurements of cloud tracers using the VIRTIS instrument on Venus Express (2006–2012) at different altitudes: daytime (red) and nighttime (blue). (c) Titan vertical profile of the zonal wind as measured from different techniques. (a) and (b) from Sánchez-Lavega et al. (2017), (c) adapted from Hörst (2017)

different wavelengths. Notoriously are the Y- and Psi-shaped features prominent at ultraviolet wavelengths where an unknown chromophore absorbs solar radiation. Another is the large arc-shaped feature extending from north to south observed at infrared wavelengths.

The superrotation of Venus atmosphere is due to the angular momentum stored in the atmosphere and its meridional and vertical transport. Atmospheric waves, the solar (thermal) tide and eddies generated by different types of dynamical instabilities are the essential ingredients that drive its general circulation. The heating and cooling rates, including the effects of the clouds, are also essential in modeling Venus global motions. Models show that the superrotation is generated by the transport of angular momentum upwards from the surface and poleward (between latitude circles) by a thermally direct Hadley cell and, equatorward by eddy momentum fluxes. Other important mechanisms intervening in the superrotation are viscous phenomena at the planetary surface due to a combination of torques produced by frictional and turbulent exchanges in the boundary layer and with topography.

Titan is Saturn's major satellite and the second largest in the solar system (Table 1). It has a dense nitrogen atmosphere. There are few measurements of atmospheric motions, most of them in the deep and middle atmosphere from the surface to about 140 km in height. The descent of the Huygens probe in 1995 allowed obtaining the vertical zonal wind velocity profile at the entry site (Fig. 1c). Like Venus, the zonal winds increase from zero to about 40 ms^{-1} at 60 km (resulting in a vertical shear $\partial u / \partial z = 0.7 \text{ ms}^{-1}/\text{km}$) and after a velocity minimum at 80 km, they increase again to reach 100 ms^{-1} at $z = 120\text{--}140 \text{ km}$ ($\partial u / \partial z = 1.7 \text{ ms}^{-1}/\text{km}$). This means that Titan's atmosphere is in a superrotating state. Above this altitude, the superrotation reinforces again with zonal winds reaching velocities of $\sim 150\text{--}300 \text{ ms}^{-1}$ from 200–300 km and up to 340 ms^{-1} at the thermosphere at $z = 1000 \text{ km}$. These winds have been retrieved using indirect methods as the thermal winds resulting from a cyclostrophic balance between the pressure gradient force and centrifugal force, and from direct

measurements of Doppler shifts in spectral lines. Like Venus, polar vortices form in both hemispheres of Titan although their aspect looks different. The Huygens probe allowed also to measure meridional winds with velocities $< 1 \text{ ms}^{-1}$ from the surface up to 20 km altitude.

Because Titan is like Venus a slowly rotating body, the fundamental mechanisms involved in its general circulation are similar to those of Venus. The low value of the Coriolis force allows the formation of a global tropospheric Hadley cell consisting of ascending motions in the summer hemisphere (up to 500 km altitude) and descending motions in the winter pole (down to 50 km altitude). These are the approximate altitudes where this circulating cell transports heat and momentum across latitudes. Titan has a significant obliquity (Table 1), hence seasonal changes affect its upper atmospheric circulation. Therefore, this single cell pattern can break into two cells near equinoxes.

Earth and Mars

The general circulation of the atmospheres of these two planets is driven by the sunlight energy deposited on them and in the surface and is controlled by their rapid rotation periods and inclinations of their axis of rotation (and consequently of their seasonal insolation cycle) (Table 1). Both planets have variable hemispheric surface properties that influence the motions, in the case of Mars due to different albedo markings and in the case of the Earth to the continents and oceans dichotomy, including topography. A major difference between both planets is in their mass per unit area that is 53 times higher on Earth than on Mars. The atmospheric composition and the presence of clouds and aerosols (with abundant dust on Mars close to the surface) control the heating and cooling rates. On Earth, the atmosphere is composed by two diatomic molecules (nitrogen and oxygen) lacking of a significant infrared absorption spectrum. On the contrary, in Mars, carbon dioxide is the main atmospheric compound, which possesses a rich infrared absorption spectrum, heating and cooling the

atmosphere. In addition, this carbon dioxide can condense under the low temperatures of Mars winter polar regions, generating a “condensation flow” towards and from the poles, unique to this planet. Water vapor is another key element on Earth and Mars since, besides its radiative properties, it can condense in both planets forming clouds that are much more massive on Earth than on Mars. Water vapor and its condensation are key ingredients in Earth’s tropical dynamics. The seasonal cycles of carbon dioxide, water, and dust on Mars control the variability of the atmospheric circulation.

Both planets are rapidly rotating bodies and hence the Coriolis and pressure gradient forces dominate to first order the momentum equation. When these two forces balance, the atmosphere is under a geostrophic regime. Close to the surface, the friction force must be taken into account in the momentum equation. When considering the continuity equation, the equation of state and the thermodynamic equation, the circulation outside the equatorial-tropical latitudes obeys the thermal wind equation that relates the horizontal temperature gradient with the vertical shear of the horizontal wind velocity. On Earth and Mars outside the equator, the global motions are essentially zonal, dominated by eastward jets in each hemisphere (Figs. 2 and 3). On Earth, a weak subtropical jet stream is centered at latitude $\sim 30^\circ$ and altitude ~ 12 km, and a polar jet stream is present at an altitude $z \sim 8\text{--}10$ km between latitudes $\sim 40^\circ\text{--}60^\circ$ with peak velocities of $\sim 25\text{ ms}^{-1}$ (but peak speeds reach in occasions $\sim 100\text{ ms}^{-1}$) (Fig. 2a, b). The two jets merge at some locations and times producing a single jet while at other times both jets are intense and well separated. These jets show undulations in latitude due to Rossby waves generated by the meridional gradient of the Coriolis force. The jets follow the thermal wind equation under geostrophic balance with intense vertical shear in the zonal velocity. These jets weaken above the tropopause ($z \sim 10$ km) but then increase their strength with altitude from ~ 25 km to 70 km, reaching speeds up to $\sim 60\text{ ms}^{-1}$ in the stratosphere-mesosphere. On Mars, due to the low atmospheric mass and

radiative time constant, the jet streams are strongly seasonal dependent (Fig. 3). They reach peak velocities of $\sim 100\text{--}180\text{ ms}^{-1}$ at altitudes $z \sim 35\text{--}45$ km.

In between these zonal jets, meridional circulations of a Hadley-cell type are present. On Earth, it consists of a main Hadley cell between equator and tropics ($\sim 30^\circ$ latitude) and two additional cells, the Ferrel cell (circulating in a thermodynamically indirect sense from $\sim 30^\circ$ to 60° latitude) and a polar cell (from $\sim 60^\circ$ to 90° latitude) (Fig. 2c). At the equatorial surface, the Hadley cell is in the origin of the “trade winds” (westward tilted) when converging air in the equator forms the Intertropical Convergence Zone (ITCZ). In the ITCZ, strong ascending moist and warm air forms massive cumulus cloud along a planetary-scale narrow cloudy belt. The ITCZ shows seasonal and geographical variability and is related to a number of instabilities and waves that develop in the equatorial region. On Mars, the meridional circulation consists of a Hadley circulation that varies seasonally in its meridional extent and strength. At solstices, there is a single (global) Hadley cell that moves air from one hemisphere to the other. It drives the air in opposite directions in summer and winter solstice: warm air rises in the summer hemisphere of Mars (the hottest subsolar latitudes are $\sim 25^\circ\text{--}30^\circ$) and sinks in the winter hemisphere. At equinoxes, a dual Hadley cell forms with air rising near the equator fed by a surface flow from both hemispheres.

Two additional mechanisms contribute to the global atmospheric motions on Mars. On the one hand, there is a seasonal flow due to the pressure gradient generated by the condensation of CO_2 in winter in the polar caps. This condensation flow transports heat, momentum, and mass between low and high latitudes with a velocity of $\sim 0.5\text{ ms}^{-1}$. On the other hand, the low mass of the Martian atmosphere and its low radiative time constant favors large temperature differences (tens of degrees Kelvin) between the illuminated and shadowed hemispheres, driving thermal tides that propagate in the direction of motion of the Sun in the Martian skies.

northern summer solstice; (c) northern autumn equinox; and (d) northern winter solstice. From Mars Climate Data-base (<http://www-mars.lmd.jussieu.fr/mars/access.html>)

Jupiter and Saturn

The gaseous giants (Jupiter and Saturn) and the icy planets (Uranus and Neptune) are rapidly rotating fluid bodies that lack of a solid surface. The wind speeds at the upper visible cloud level are measured with respect to the bulk rotation of the planet determined from the modulated radio emissions by the rotation of the magnetic field. This magnetic field is generated in the deep massive electrically conducting interior and its axis tilts relative to the planet rotation axis except in the case of Saturn for which both axes are parallel. This is why the bulk rotation of Saturn is not yet fixed within an interval of a few minutes. The wind speed and its direction are measured by tracking the motion of cloud features. In the upper ammonia cloud (altitude range between pressure levels $P \sim 0.5\text{--}1.5$ bar), all four planets show a dominant zonal circulation consisting of a system of jet streams showing different intensities and alternating in their East-West direction with latitude (Fig. 4).

Jupiter has about eight jets per hemisphere exhibiting maximum speeds at the equator,

where a broad eastward jet reaches velocities $\sim 100\text{--}125\text{ ms}^{-1}$, and at latitude 23° N , where a narrow strong eastward jet reach velocities up to 180 ms^{-1} (Fig. 4a). This jet breaks the symmetry between north and south hemispheres. Saturn has six jets per hemisphere with a very strong and broad eastward equatorial jet with peak speed of $\sim 450\text{ ms}^{-1}$ relative to the radio-rotation period determined by the Voyager 1 and 2 spacecraft (known as System III and used as standard) (Fig. 4b). Jupiter and Saturn westward jets are less intense than those eastward. At the poles, Jupiter shows a system of 5–6 circumpolar cyclones, while in Saturn, a single, intense cyclone with winds at periphery of $\sim 150\text{ ms}^{-1}$ is centered at each pole.

Because of the rapid rotation of these planets, the atmospheric motions are under geostrophic balance in all latitudes except in the equatorial region (typically considered between the latitudes that contain the equatorial jet, case of Jupiter and Saturn). From the measurements of the temperature field above clouds, the use of the thermal wind equation allows to infer the vertical wind

Atmospheric Circulation, Fig. 4 Mean zonal winds in Jupiter (a) and Saturn (b) measured from cloud tracking. The Jupiter profiles were obtained at different years (red in 1979; black and blue in 2000; green in 1995–2000). The Saturn profiles correspond to different years (green in

1981; black and red in 2004–2009) and pressure level altitudes in the equatorial region: ~100 mbar (red), ~500 mbar (black), and ~1 bar (green). From Sánchez-Lavega and Heimpel (2018)

shears and obtain the zonal wind speeds above the clouds. Outside the equator in both planets, the winds decrease with altitude at a rate of about $\sim 5 \text{ ms}^{-1}/10 \text{ km}$. At stratospheric altitudes above clouds (between pressure levels ~ 0.1 and $\sim 50 \text{ mbar}$) in the equatorial region, the zonal winds exhibit a vertical, cyclic pattern of alternating velocities that propagate slowly downwards with a period of 4–5 years in Jupiter and ~ 15 years in Saturn. These are known as the Jupiter quasi-quadrennial oscillation (QJO) and as Saturn Equatorial Oscillation (SEO).

Deeper the upper cloud, in the weather layer where most clouds form (~ 1 – 5 bar in Jupiter, ~ 1 – 10 bar in Saturn), winds have velocities similar to those found in the upper cloud according to dynamical studies of convective storms. In December 1995, the Galileo probe penetrated the Jovian atmosphere at latitude 7°N in a peculiar dynamical region known as a “hot spot.” The direct measurement of the winds showed to increase from 100 ms^{-1} in the upper cloud to 160 ms^{-1} down to a depth of 24 bar . Beneath the weather layer, Jupiter and Saturn wind system extends deep in the atmosphere as determined by recent precise measurements of the gravity and magnetic fields by Juno spacecraft in Jupiter and Cassini spacecraft in Saturn. Accordingly, the cloud-level winds on Jupiter (Saturn) extend with very little decay down to a depth of around 2000 km (7000 km) and then decay rapidly in the electrically semiconducting region within the next 600 km (1000 km) where their value reduces to about 1% of that at the cloud-level.

Basically two theories have been proposed to explain the atmospheric motions on both planets. The zonal winds could be driven by convection in a deep spherical shell due to the release of stored internal energy in both planets coupled to their rapid rotation. This rotation organizes convection in axially oriented geostrophic columns that through dynamical stresses feeds the energy into zonal flows. The other hypothesis is that the zonal winds are driven by the solar energy deposited in the shallow upper weather layer, in a manner

similar to what occurs on Earth. The zonal winds form from the turbulent motions due to a variety of dynamical phenomena in the stably stratified weather layer.

Uranus and Neptune

As Jupiter and Saturn, the zonal wind profile of both planets has been measured from the tracking of cloud features. In contrast to the two giants, Uranus and Neptune, have comparatively simple circulations, both highly zonal and characterized by a broad retrograde equatorial jet with direction opposed to the planetary rotation (retrograde) and with high-latitude prograde jets (in the direction of rotation of the planet) (Fig. 5). In Uranus the equatorial velocity reaches $\sim -50 \text{ ms}^{-1}$ and in Neptune -400 ms^{-1} . The two mid-latitude symmetric eastward jets in Uranus (latitude 55°) reach velocities of $\sim 230 \text{ ms}^{-1}$. In Neptune, it is not evident that this symmetry exists and there is only a confirmed jet close to the pole at 75°N with peak velocity of 275 ms^{-1} . The atmospheric circulation in both planets is surprisingly similar considering their very different inclinations of the rotation axis and their internal heat sources. Also surprising is the high speeds of their jets which, considering the differences in the strengths of their energy sources, suggests that it is the rapid rotation that essentially drives the atmospheric circulation. The available data on their structure of the gravity field and state-of-the-art interior models suggests the winds to be confined to a thin weather layer of no more than 1600 km on Uranus and 1000 km on Neptune, shallower than the deep winds of Jupiter and Saturn.

Basic Methodology

The study of the atmospheric circulation is based on the determination of the intensity of the winds in the three directions: zonal (along latitude circles, East-West), meridional (along meridian circles, i.e., across latitude circles, North-South), and vertical (radial or perpendicular to the plane tangent to the spheroid surface under consideration).

Atmospheric Circulation, Fig. 5 Mean zonal winds measured from cloud tracking since 1986 in Uranus (a) and 1989 in Neptune (b). The solid curves are fits to the individual data points measurements compiled by L. A. Sromovsky as shown in Sánchez-Lavega and Heimpel

(2018). The dashed curve in the Neptune profile is a fit to additional data points measured in the equatorial region where wind data have a large uncertainty due to temporal changes or altitude differences in the cloud tracers as shown in Hueso and Sánchez-Lavega et al. (2019)

The techniques and methods used in the study of atmospheric motions are based, on the one hand, on the direct observation and measurements in situ of the wind (platforms, rovers, soundings by probes), and on the other hand, on remote sensing methods using telescopes on Earth and in space (orbiting the Earth) and with spacecrafts visiting the planets (flybys, orbiters). The velocity and direction of the wind is measured directly using tracers of the fluid motion, such as clouds and aerosols, or of the gas itself through its spectral lines by means of the Doppler effect. Indirectly it can be determined from measurements of the temperature or pressure field and simple mathematical approximations to the fluid motion, such as the thermal wind equation or the meridian cell circulation. Numerical simulations of the atmospheric circulation under a variety of mathematical approaches and methods, known as general circulation models (GCM), are used for the

interpretation of the observable magnitudes and for short-term weather forecast and long-term climate predictions.

Key Research Findings

Venus: Three-dimensional structure of the winds, existence of traveling and stationary planetary waves, and presence of polar vortices in both hemispheres.

Venus and Titan: State of superrotation of their atmospheres.

Earth: Mid-latitude jet streams, planetary-scale Rossby waves, and system of three meridional cells per hemisphere. Existence of a single polar vortex in each hemisphere.

Mars: System of mid-latitude jet streams and interhemispheric Hadley cell, and their seasonal variability.

Jupiter and Saturn: System of stable alternating jets with latitude and presence of strong and wide in latitude prograde equatorial jets. The vertical structure of the winds in both planets and their deep extent, decaying to zero velocity at the electrically conductive deep layer.

Jupiter poles: Existence of a system of five to six cyclones surrounding both poles.

Saturn: Existence of a single polar vortex (an intense cyclone) in each hemisphere.

Uranus and Neptune: The atmospheric circulations dominated by the rotation of the planet with intense retrograde equatorial jets and prograde jets (one per hemisphere in the case of Uranus) at high latitudes.

Future Directions

Venus: Improve the GCM models of the superrotation and explain the nature of the planetary-scale waves and the polar vortices.

Mars: Measurement of the three-dimensional structure of the winds and their seasonal variability. Improve the three-dimensional structure of the heating and cooling rates due to aerosols (suspended dust and clouds) and their effects on the GCM models.

Jupiter and Saturn: Development of GCM models to explain the nature of their circulations at cloud level and the deep vertical structure of the wind system.

Uranus and Neptune: Development of GCM models to explain the nature of the observed circulations at cloud level and infer the vertical structure of the wind system from remote sensing measurements.

Titan: Characterization of the circulation as a function of altitude and latitude and development of GCM models.

General observations: New measurements of the relevant parameters to determine the planetary atmospheres circulations from space missions (flybys, orbiters, probes and platforms, and rovers) and from remote sensing using large optical and infrared ground-based and space telescopes, and radio-telescopes arrays.

Atmospheric Modeling, Gray Gas Model

Raymond Pierrehumbert
Department of Physics, Clarendon Laboratory,
University of Oxford, Oxford, UK

Definition

For most atmospheric gases the optical thickness has an intricate dependence on wavelength. This complicates the solution of the radiative transfer equations, since the fluxes must be sought individually on a very dense grid of wavelength, and then the results integrated to yield the net atmospheric heating. The radiative transfer equations become much simpler if the optical thickness is independent of wavelength, which is known as the gray gas approximation. For gray gases, the relevant equations can be integrated over wavelength, yielding a

single differential equation for the net upward and downward flux. With the exception of clouds of strongly absorbing condensed substances like water, the gray gas model yields a poor representation to radiative transfer in real atmospheres, but the gray gas model is nonetheless a powerful theoretical tool for exploratory work in planetary atmospheres. It is also valuable as a radiation scheme in idealized general circulation modeling studies.

Atmospheric Modeling, Non-gray Gas Model

Raymond Pierrehumbert
Department of Physics Clarendon Laboratory,
University of Oxford, Oxford, OXON, UK

Definition

For real gases, as well as for gray gases (the gray gas approximation assumes that the atmosphere is transparent to solar radiation and possesses an absorption coefficient that is constant throughout the emitting infrared wavelength region – hence “gray” – and is independent of pressure and temperature), heated by infrared emission from the lower boundary, the temperature decreases with distance from the boundary (normally, the planetary surface). Real gases behave as if they are

optically thick near the ground, exhibiting strong convectively unstable temperature gradients there and only a small temperature jump between the ground and the immediately overlying air. For most atmospheric gases the optical thickness has an intricate dependence on wavelength; therefore the radiative transfer equations must be solved individually on a very dense grid of wavelength and then the results integrated to yield the net atmospheric heating. The upper atmosphere is considerably colder than the gray gas skin temperature, since (by Kirchoff's law) the atmosphere radiates efficiently in the strongly absorbing parts of the spectrum, but the radiation illuminating the upper atmosphere is depleted in this portion of the spectrum.

Atmospheric Modeling, Radiative-Convective Equilibrium

Daniel D. B. Koll
Department of Earth, Atmospheric and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, MA, USA

Definition

Radiative-convective equilibrium describes the hypothetical mean state of an atmospheric

column that is subject to heat transfer by radiation as well as convection. Radiative-convective equilibrium provides a useful approximation for the average vertical temperature structure of planetary atmospheres, which in turn determines a planet's surface climate as well as its observable state.

Overview

Radiative-convective equilibrium is a generalization of the concept of radiative equilibrium. An atmosphere is in pure radiative equilibrium when each part of the atmosphere radiatively emits as much energy as it absorbs. The theory of radiative equilibrium found early applications in explaining the thermal structure of the Sun's atmosphere and Earth's stratosphere.

Radiative equilibrium is a poor approximation for many planetary atmospheres, however, because physical processes other than radiation can also redistribute energy. Prime among them is convection, which arises from an atmosphere's turbulent motions. Convection redistributes energy by transporting heat as well as causing atmospheric gases to condense, which releases latent heat. In atmospheres without strong absorbers of stellar irradiation, pure radiative equilibrium tends to be unstable to turbulence. Turbulence can be triggered by strong vertical gradients in temperature, gradients in atmospheric composition, or temperature jumps near a planet's surface and cloud decks. These instabilities will cause a state of radiative equilibrium to evolve into a state of radiative-convective equilibrium (Fig. 1).

In radiative-convective equilibrium, each part of the atmosphere emits as much heat as it absorbs from radiation and convection combined. The assumption of radiative-convective equilibrium is commonly used in 1D climate models and retrieval models for planetary observations.

While the assumption of radiative-convective equilibrium is often a good approximation to the mean vertical structure of planetary atmospheres, its application becomes more questionable on

Atmospheric Modeling, Radiative-Convective Equilibrium, Fig. 1 The interplay of radiation and convection sets the mean vertical structure of planetary atmospheres. In this example, the atmosphere is largely adiabatic due to convection near the ground and evolves into a radiatively dominated profile near the top of atmosphere. (Figure from Pierrehumbert (2010))

planets with large horizontal temperature gradients. Examples include Earth's atmosphere at high latitudes, in which Earth's rotation prevents atmospheric motion from evenly redistributing heat, and tidally locked exoplanets, many of whom exhibit strong thermal contrasts between day- and nightside.

[Single-column model](#)

Definition

One-dimensional (1D) models represent a planet's atmosphere as a vertical atmospheric column. 1D models are particularly useful for studying the flow of energy through an atmosphere and typically represent a planet's mean vertical structure while neglecting any horizontal inhomogeneity. Important applications of these models have included pioneering global warming predictions on Earth, defining the limits of the habitable zone and interpreting planetary remote observations.

Overview

The physics of heat transfer via radiation was developed in the nineteenth and early twentieth centuries. Radiative transfer theory found early applications in observations of stars and understanding the structure of stellar atmospheres. At the same time, observational capabilities expanded that prompted the application of these theories to planets, from early meteorological balloon measurements that discovered the stratosphere on Earth to remote spectroscopic measurements of solar system bodies.

By virtue of capturing the flow of energy through an atmosphere, 1D models can be used to understand an atmosphere's vertical thermal structure and the mean energy balance that determines its surface climate. For the same reason, 1D models are also widely used to model atmospheric

photochemistry and atmospheric escape processes. In addition, 1D models can be used as forward or inverse models to interpret measurements that probe different atmospheric altitudes, such as remote spectra of planets.

In the context of Earth's climate, 1D models produced some of the first quantitative estimates for how changes in CO₂ levels impact Earth's surface temperature. In the context of planetary habitability, 1D models have been used to identify the physical mechanisms that define the edges of the habitable zone, including the runaway greenhouse and the moist greenhouse. Finally, 1D models are widely used to interpret spectra taken of other planets; this has included remote sensing data of Mars, Venus, and Titan in the solar system and, more recently, spectra of exoplanets.

The physics that is best resolved by 1D models is the vertical flow of energy through a planet's atmosphere, in particular the redistribution of heat by radiative transfer. Other physics that can be captured well in 1D models are gravity and some atmospheric escape processes; conduction, which becomes important at low pressures, such as in Earth's thermosphere or in Pluto's atmosphere; and an atmosphere's gas-phase chemistry.

1D models often include physical processes that cannot be explicitly resolved within the model assumptions but can be mimicked through parameterizations. A prime example is convection and its effect on cloud cover. Convection arises from the turbulent motions of differentially heated gas parcels and is of first-order importance for the vertical redistribution of energy and chemical species. 1D models cannot resolve these motions but often parameterize their effect as vertical diffusion or use alternative convection schemes. Other processes which are parameterized in 1D models include precipitation and the formation of rain; ice-albedo feedbacks; and heterogeneous chemistry, which involves chemical reactions mediated by spatially inhomogeneous aerosol and cloud particles.

Physical processes that are not represented in 1D models tend to be associated with strong horizontal inhomogeneity. Inhomogeneity can arise from various sources, including the fact that planets are not uniformly irradiated by their star and variations in surface topography. Other

typical shortcomings of 1D models include their inability to resolve large-scale atmospheric fluid motions and the neglect of effects that arise from a planet's curvature. Despite these limitations 1D models remain some of the most flexible theoretical tools available, with widespread use in exploratory work and inverse modeling.

Atmospheric Processes, Escape

Raymond Pierrehumbert
 Department of Physics, Clarendon Laboratory,
 University of Oxford, Oxford, UK

Definition

Atmospheric escape refers to the loss of a planet's atmosphere to space. Broadly speaking, escape may be energy-limited or diffusion-limited. For the energy-limited case, permanently removing a molecule from a planet's atmosphere can be compared to sending a rocket from Earth to space: One must impart enough velocity to the object, and in

the right direction, to allow the object to overcome the potential energy at the bottom of the gravitational well and still have enough kinetic energy left over to allow the object to continue moving away. The study of atmospheric escape in this case thus amounts to the study of the various ways in which the necessary energy can be imparted to molecules to reach the escape velocity, which is the minimum velocity an object needs in order to escape to infinity, provided no drag forces intervene.

Overview

The thermal escape velocity is obtained by equating initial kinetic energy to the gravitational potential energy:

$$\begin{aligned} \frac{1}{2} mv^2 &= GM_P m/r, \\ v &= \sqrt{2GM_P/r} = \sqrt{2gr} \end{aligned}$$

where m is the mass of the object (molecule in the present case), v its speed, r its initial distance from the center of the planet, M_P the mass of the planet, G the universal gravitational constant, and g the acceleration of gravity at distance r from the planet's center. In order to allow a molecule to escape, enough energy must be delivered to the molecule to accelerate it to the escape velocity. Since the kinetic energy of a molecule with mass m is $\frac{1}{2} mv^2$, light molecules such as H_2 will move faster and hence escape more easily than heavier molecules such as N_2 , given an equal delivery of energy. Dissociation of a molecule such as CO_2 or H_2 into lighter individual components also aids escape. Using the formula for escape velocity, we can define the escape energy of a molecule with mass m as mgr . For escape of N_2 from altitudes not too far from the Earth's surface, this energy is 2.9×10^{-18} J; for H_2 , the escape energy is only 0.2×10^{-18} J.

Atmospheric escape may be categorized as follows:

- Thermal (Jeans) escape – molecular speeds generally obey the Maxwell-Boltzmann distribution. Fast-moving species in the high-energy tail of the distribution may attain enough energy to escape the atmosphere. The general thermal energy of the atmospheric gas ultimately comes from, e.g., absorbed stellar radiation or from heat leaking out of the interior of the planet.
- Nonthermal escape mechanisms. Here, a “collisional process” energizes gas species above the escape barrier. For example, “ion exchange” involves charged species, e.g., hydrogen cations (H^+), which are accelerated in the planet's magnetic field to high energies. If the H^+ acquires an electron from a neighboring neutral species, it is converted into a neutral, high-energy atom (H^*) which can escape the atmosphere. Nonthermal escape can also involve interaction of, e.g., atmospheric species with the stellar wind (e.g., “sputtering” refers to the collisional ejection of a neutral species from the atmosphere by incoming high-energy species). “Impact erosion” refers to atmospheric escape driven by high-energy impacting material.

Definition

Atmospheric retrieval for exoplanets refers to the inference of atmospheric properties (atmospheric composition, thermal structure, clouds and hazes) of an exoplanet given an observed spectrum.

Overview

Objectives for Exoplanets

A spectrum of an exoplanet contains a lot of information about the atmosphere (atmospheric composition, thermal temperature, climate, clouds and hazes), coded into the molecular emission/absorption lines and bands. The goal of atmospheric retrieval is to retrieve these atmospheric properties from an observed spectrum. Measuring the molecular abundances in exoplanetary atmospheres is fundamental to understand the diversity, formation, and evolution of exoplanets. For the astrobiological context, the search for life on exoplanets is mostly focused on the detection of

potentially biogenic gases like O_2 , CH_4 , and N_2O . Accurate characterization of the whole atmosphere (composition and climate) and surface (temperate conditions, presence of liquid water, . . .) is required to give credit to a potential biological activity.

Principle

The principle of atmospheric retrieval is to compare the observed spectrum and data to several simulated spectra computed with an atmospheric model. A statistical method is applied to estimate the most likely atmospheric parameters allowing “to fit the data.”

Atmospheric Models

There are two main kinds of atmospheric models applied for retrieval:

1. **Self-consistent models** which simulate realistic temperature and composition profiles as well as spectra. These physical models include radiative transfer, chemistry (equilibrium or nonequilibrium chemistry), and potentially cloud formation. Since these atmospheric models can be computationally expensive, a grid of simulations for different parameters is usually computed before applying statistical methods to derive the parameters for the observed data. Self-consistent models cannot explore a too large parameter space and the retrieval can be biased by the physics included in the model. They are particularly useful for limited dataset (low signal-to-noise ratio or few points) compared to parametric models.
2. **Parametric models** simulate atmospheres using a limited number of atmospheric parameters and with limited assumptions on the physics and chemistry. A widely used thermal structure model is the model from Guillot (2010), using only five parameters (irradiation, internal heat, heat redistribution, visible and infrared extinction coefficients). These fast models allow to explore a large parameter space. They are not biased by the physics/

chemistry used and are really data-driven. However, they can allow degenerated solutions or physically impossible solution when only limited data is available (not high enough signal-to-noise ratio, spectral resolution, and spectral range).

Parametric models are ideal for exoplanets for which there still so many unknowns. However, the quality of spectra obtained by current telescopes is generally not high enough to make retrieval based on parametric models more accurate than with self-consistent models. The situation will likely change with future telescopes as JWST, ELTs, and ARIEL.

Statistical Methods

A modest atmospheric retrieval with the Guillot temperature profile (Guillot 2010) +3 molecule abundances (e.g., H₂O, CH₄, CO) and clouds (assuming gray cloud and with the cloud top as free parameter) corresponds to 10 free parameters. The full exploration of this parameter space for the atmospheric retrieval of an exoplanet would require a huge number of models, not achievable in a reasonable amount of time. This is why statistical methods are used to quickly explore the parameter space, focusing on the regions where are the best fits. Three methods are mostly used (see Table 1 in Madhusudhan 2018).

Optimal Estimation Method

The Optimal Estimation (OE) method is widely used for atmospheric retrieval of the Earth and Solar System planets. This method determines the best fit after a few iterations by optimizing the likelihood function using a nonlinear least squares minimization scheme. A priori probability distributions (called priors) can be specified for parameters which are already quite well constrained. The OE method is favored for high quality dataset and is limited for cases with strong degeneracies.

Markov Chain Monte Carlo (MCMC)

The MCMC method aims at exploring the parameter space a by random walk starting from an

initial guess. The parameters used for a next step are determined from the current step with a pre-defined distribution as a Gaussian distribution. MCMC determines well the posterior distribution but is not very efficient for cases with multiple plausible solutions

Nested Sampling

The Nested Sampling is quite similar to the MCMC but differs concerning the sampling of the parameter space. Instead of doing a chain starting from an initial guess, the Nested Sampling starts from several initial points, fixed by the prior distribution. At each iteration, the point with the lowest likelihood is discarded and replaced by a new point with a higher likelihood. The contour formed by these points shrinks after each iteration toward a solution. This method is computationally efficient and well suited for large parameter spaces, as it is generally the case for exoplanets.

Difficulties for Exoplanets and Future Missions

Stratospheric Thermal Inversion

Initial Spitzer eclipse observations suggested the presence of stratospheric thermal inversions on very hot exoplanets. These conclusions relied on the differences of thermal emission in the 3.6, 4.5, 5.8, and 8.0 μ m Spitzer bandpasses. Corrections of some systematics ruled out the stratospheric thermal inversion in some hot exoplanets (Diamond-Lowe et al. 2014). That issue illustrates how atmospheric retrieval can be misleading by low quality data.

Clouds/Hazes

The transit observations of exoplanets revealed that most of them are cloudy or hazy. These condensate clouds or photochemical hazes mask atmospheric molecular absorption, producing flat transit spectra. They represent a major issue for atmospheric retrieval.

Water Abundance

A major question for exoplanets is to determine the water abundance of exoplanetary

atmosphere and how is it related to the planetary mass. Following the Solar System giant planets, we can expect that the metallicity (i.e., the water abundance) decreases with the planetary mass. Several measurements of water abundance have been performed with HST data of hot giant planets. However, the conclusions differ depending on the retrieval model and how clouds are treated (see Sing 2018; Pinhas et al. 2019).

The 3D Nature of Exoplanets

Most of atmospheric retrieval codes assume that limbs or observed side are homogeneous. However, strong contrasts in temperature and cloud cover can exist between the west and east terminators, and partial cloud cover can be present on the dayside. In addition, 1D atmospheric models used phase-curve retrieval miss the heat redistribution by the atmosphere. New methods combining two terminator profiles (Line and Parmentier 2016) or doing 2D/3D retrieval for phase curves (Irwin et al. 2020) have been developed to take in account these 3D effects.

Future Telescopes

Atmospheric retrieval is very promising for JWST and ARIEL. These space telescopes will obtain transit and emission spectra of hundreds of exoplanets from 0.6 to 28 microns (for JWST) and from 0.5 to 8 microns (for ARIEL). These large spectral ranges allow to cover absorption bands of several molecules (H_2O , CH_4 , CO , NH_3 , CO_2 , PH_3 , HCN , C_2H_6 , FeH , TiO , VO , ...). They probe in the mid-infrared, where the effects of clouds are reduced. In parallel, cross-correlation technics applied to high resolution spectra from ELTs will also allow to retrieved temperature structure and molecular abundances of exoplanets (Brogi and Line 2019).

Atomic fine structure cooling is one of the processes by which ► [interstellar medium](#) material can lose thermal energy. Atomic and molecular hydrogen collisions excite the fine structure components of ground state terms in atoms and atomic ions – e.g., in neutral carbon and oxygen atoms and in C^+ – and these subsequently decay radiatively with the escaping photon leading to a net cooling of the gas.

Definition

By **Atomistic Computer Simulation** methods, one generally refers to computational approaches

explicitly treating each atom of a given chemical system of interest, ranging from gas-phase quantum chemistry to condensed-phase molecular dynamics. These methods have long demonstrated their capability to explain and predict the chemical behavior of a variety of systems at different scales (of length and time), and different conditions, but only recently begin to be adopted within the prebiotic chemistry and astrobiology/origins of life research field (Perez-Villa et al. 2020). A crucial requirement for those methods to be useful, in the context of prebiotic chemical reactions, is to accurately model the electronic structure of the systems to describe the breaking and formation of chemical bonds. To this aim, different available computational chemistry methods, such as those based on molecular orbital theory (Szabo and Ostlund 1989), density functional theory (Parr and Yang 1995), or empirical valence bond theory (Warshel 1980), are able to accurately describe and predict the reorganization of electronic structure connected to changes in chemical bonding. Modern theoretical and computational challenges, particularly needed for astrobiology and prebiotic chemistry, are focused on the efficient exploration of complex, multi-dimensional chemical networks to determine, under a variety of possible geochemical environments, the most relevant chemical pathways. Thanks to the emergence of novel, innovative theoretical approaches, and to the increase of available computer power, such methods can now be applied to challenging prebiotic problems, bringing valuable insights that are complementary to experiments.

Overview

Atomistic computer simulations in chemistry comprise different types of approaches, such as classical molecular dynamics, semiempirical simulations, and ab initio quantum chemistry methods, all characterized by the explicit and generally individual treatment of each atom in the chemical system of interest. Among those approaches, ab initio methods are particularly relevant in prebiotic chemistry, as they are very

accurate in computing minima (corresponding to reactants, intermediates, and products) and barriers in the energy landscape of a quantum system containing many atoms and electrons. One generally refers to “*ab initio* quantum chemistry,” or simply “quantum chemistry (QC),” to identify approaches in which the atomic interactions are described “*ab initio*,” a Latin term that means “from the beginning” or “from first principles.” *Ab initio* quantum chemistry is indeed based on quantum mechanics, not relying on experimental information or empirical models.

QC calculations aim for the “exact” solution of the Schrödinger equation corresponding to the molecular Hamiltonian. Those methods have in general an elevated computational cost, and typically one is able to model relatively small systems (up to few tens of atoms); however, this is the most established tool to study at the atomic scale the properties and reactivity of molecular systems. Among the many methods developed in the last decades with the aim of obtaining an accurate, albeit approximate, numerical solution of the Schrödinger equation, the Hartree-Fock (HF) one was the first to provide useful and quantitative insight. In the HF equations, the electronic wave-function is approximated in an effective way, and the molecular orbitals are optimized by a numerical iterative self-consistent procedure. However, its formulation inaccurately describes states in which electron correlation plays an important role. In this regard, one of the main challenges has been to develop new approaches that include the electron correlation at a reasonable computational cost, typically known as post-Hartree-Fock methods.

Over the decades, a less accurate than QC but more effective class of computational methods for physics and chemistry, based on Density Functional Theory (DFT) (Becke 2014; Hohenberg and Kohn 1964; Kohn and Sham 1965), has emerged and become popular. DFT-methods are centered on the Hohenberg-Kohn theorem, which proves that the ground state energy of a multi-electron system is univocally determined by a functional of the ground state electronic density. The electronic density is a function of three spatial coordinates only, and not of the coordinates of all

N electrons like in the case of the QC wave function, which makes its treatment more efficiently manageable. As a consequence, and thanks to the availability of efficient approximations and algorithms, DFT-techniques provide, with respect to higher-level QC methods, a more powerful and faster way to obtain information about the structure and energy of a chemical system, at least in its electronic ground state. Conversely, low-temperature/gas-phase excited-state chemistry (for example, photochemistry in the interstellar medium) is better and more accurately described by QC approaches.

In many chemical problems, especially in prebiotic chemistry, it is paramount to assess the effects of the environment. This might comprise the presence of solvent molecules, the effect of ions and/or pH, the interaction with mineral surfaces, and so forth. In addition, for several applications it is essential to take into direct account the effect of temperature, beyond normal-mode extrapolations like the quasi-harmonic approximation, and sometimes pressure. Hence, in several cases performing QC simulations at absolute zero temperature and gas-phase might not be a very suitable choice (Voth and Hochstrasser 1996). Among the most powerful strategies to simulate complex chemical systems, a central place is held by *ab initio* molecular dynamics (AIMD) (Car and Parrinello 1985; Marx and Hutter 2009; Tuckerman 2002). AIMD combines the quantum treatment of the electronic degrees of freedom, with the numerical integration of Newton’s equation of motion, where quantum-calculated forces act on the atoms. In general, the typical timescale for individual AIMD trajectories ranges between tens and hundreds of picoseconds, with typical time steps in the range 0.1–0.5 fs. In principle, AIMD simulations are ideally suited to study the mechanisms, thermodynamics, and kinetics of chemical reactions at a given pressure and temperature. An extremely long trajectory of the system, generated from accurate forces, would ergodically sample fluctuations within metastable states as well as all possible transitions among them.

However, DFT-based AIMD simulations are presently typically limited to the subnanosecond

timescale. Of course, because of free-energy barriers, the experimental timescale of most chemical reactions is immensely slower, ruling out straightforward computer simulations. To cope with timescale limitations, but also to get fundamental insight that is not automatically provided by a bare long MD trajectory, a number of different so-called enhanced sampling approaches were introduced in the last few decades, such as umbrella-sampling (Torrie and Valleau 1977), or metadynamics (Laio and Parrinello 2002). However, even with the help of enhanced-sampling, the widespread exploitation of MD simulations in the study of chemical reactions has been slowed by the lack of general-purpose formulations of reaction coordinates. In particular, it is challenging to design coordinates that fully include the important role of solvent degrees of freedom (Ensing et al. 2006; Prasad et al. 2013) and that are general enough to be applied to a range of diverse reaction mechanisms. Ref. (Pietrucci and Saitta 2015) proposed a new way to tackle this problem. The method deals in the same formal way (namely, in the same space of coordinates) with gas phase and solutions, allowing a direct comparison of the two environments and an easier assessment of the effects of a given solvent on reaction pathways. Several impactful applications of this novel approach have been successful in describing the prebiotic synthesis, in aqueous solution, of RNA nucleotides (Pérez-Villa et al. 2018), and of amino acids (Saitta and Saija 2014; Pietrucci et al. 2018; Magrino et al. 2021).

The most advanced methods in computational physics and chemistry can play a particularly useful role in the modeling and simulation of prebiotic chemical reactions. The level of accuracy has increased significantly, and the implementation of highly demanding algorithms is becoming more feasible, allowing the investigation of very specific and complex problems in physics and chemistry. Simulations are notably very effective in the determination of free-energy landscapes based on reaction coordinates built from the structural topological properties of the reactants and the products. However, the need to describe, at the quantum level, the forces acting between atoms

and the complexity of the calculations therein have until now only permitted the processing of reactions of very small systems in solutions. Consequently, the work undertaken until now in the field of prebiotic chemistry and the molecular origins of life is still in its preliminary stages.

Synonyms

[Adenosine triphosphate](#); [pppA](#)

Definition

ATP is one of the four activated nucleotides incorporated into [RNA](#) by RNA polymerases. It is also extremely important in biochemistry as a high-energy molecule that releases the energy needed for many metabolic reactions by coupling hydrolysis into ADP and inorganic phosphate, or

AMP and pyrophosphate, with various synthetic and mechanical processes. The formation of ATP in living organisms takes place through two main biochemical pathways: substrate-level phosphorylation (in which phosphate is transferred to ADP from activated phosphorylated intermediates) and membrane-associated processes (found in respiration and photosynthesis).

Although prebiotic phosphorylation may have led to ATP from adenosine, ATP is usually not considered to have been abundant in prebiotic environments, and polyphosphates have been proposed as alternative primordial energy carriers. In prebiotic oligonucleotide synthesis, adenosine 5'-phosphoimidazolide was often used in place of ATP.

Definition

Enzymatic activity that catalyzes the decomposition of adenosine triphosphate (ATP) into adenosine diphosphate (ADP) and phosphate (Pi). A protein with ATPase activity.

Overview

The term ATPase applies to the activity of any *enzyme's* ability to decompose *ATP*, including metabolic enzymes involved in anabolic processes that need energy, as well as enzymes promoting *transport* across *membrane*. In the former case, the enzyme decomposes ATP using the energy liberated to do work; for instance, enzymes such as DNA helicases, RecA protein, AAA proteins, or the muscle contraction protein myosin

hydrolyze ATP, applying the liberated *free energy* directly to their functions. In other cases, i.e. glutamine synthetase, decomposition of ATP is performed in two steps, helping to perform chemical work, phosphorylating a substrate or enzyme in a first step, and releasing the *phosphate* (Pi) in a second step. Sometimes this type of reaction involves the transfer of pyrophosphoryl or adenylyl groups instead. There are many known ATPases, which promote ATP *hydrolysis* coupled to transport solutes across membranes into another compartment. These are integral membrane proteins called transmembrane ATPases, and there are many different types found in all kind of organisms, performing functions in which energetic exchanges are quantitatively quite relevant. These include at least five general types of this kind of ATPases: F (F comes from original name of the enzyme: Coupling Factor (CF)), V (vacuolar), A (archaeal), P (phosphate), and ABC (ATP-binding cassette)-multidrug transporters. Because of their mechanism of functioning, the three-first ones indicated are rotary ATPases. An additional rotary ATPase, specifically fueled by Na⁺ and named N-ATPase, will not be addressed here.

F-ATPases are present in the plasma membrane of *bacteria*, *mitochondrion* inner membrane, and thylakoid membranes of chloroplasts of photosynthetic *eukaryotes*, A-ATPases are found in *Archaea* and some *extremophilic* bacteria, and V-ATPase are located in the endomembrane of intracellular compartments of eukaryotic cells and the plasma membrane of several specialized cells. In vitro, all are reversible enzymes able to promote the generation of a *proton motive force* (PMF) at the expense of ATP hydrolysis or to synthesize ATP from ADP and Pi using a pre-existing proton gradient. In this second type of function, the enzyme is more appropriately named *ATP synthase*. However, in vivo, mitochondrial and chloroplast enzymes only function as ATP synthases, V-ATPases only perform the hydrolytic reaction, and bacterial enzymes can work in both ways depending on growth conditions. The process of ATP synthesis is often called oxidative phosphorylation. In the case of fermenting bacteria, which lack an electron transport chain (to produce a proton motive force) and cannot

perform oxidative phosphorylation, the enzyme acts as a real ATPase producing a proton gradient, which is used to energize other *transport* processes.

Structurally, F-ATPases are related to V-ATPases and A-ATPases, but each of these groups presents differential characteristics, as well as differences among those of the same type but in different organisms have been observed. For instance, the plant's F-ATPases have structural characteristics that allows their redox control (Hahn et al. 2018; Yang et al. 2020), or adaptations to an environment with high pH of a thermo-alkaliphilic bacterium has been described implying changes in the α subunit (McMillan et al. 2007). In F-ATPases, also called F_1F_0 -ATPases, a F_0 complex of proteins integral to the membrane is a transmembrane proton translocase, and the F_1 protein complex, at the surface of the membrane, is a molecular machine that can either decompose ATP, promoting the passage of protons through F_0 uphill the protons gradient, or transform the energy liberated by the passage of protons, downhill the gradient, through F_0 , into chemical energy, thus synthesizing ATP from ADP and P_i . The insertion of the enzyme in the membranes is quite relevant for ATP synthase function (Liu et al. 2021). Both complexes consist of assemblies of several subunits that together form a rotary motor. Binding of protons to F_0 causes the rotation of some of the subunits, which together with the subunits of F_1 conform three binding sites for ADP and P_i . The complex undergoes rotationally conformation changes through different affinity states, in one of which ADP and P_i can react before the synthesized ATP is released (rotational catalysis). The equivalent protein complexes in A-ATPases or V-ATPases are named A_1/A_0 or V_1/V_0 , respectively. Sometimes the expressions R_1 and R_0 are used referring to the two components in a general form. R_0 and R_1 complexes are bound through two kinds of stalks, a central one involved in the rotational coupling between both complexes, and one (F-ATPases) (Fig. 1), two (A-ATPases), or three (V-ATPases) (Fig. 2) peripheral stalks that connect the two complexes (Colina-Tenorio et al. 2018). Moreover, the F-ATPases found in mitochondria form dimeric structures by interactions

ATPase, Fig. 1 Model of the structure and function of F-ATPases. OSCP (oligomycin sensitivity conferral protein) is the mitochondrial-F-ATPase subunit corresponding to δ subunit in other F-ATPases. Subunit b' is a variant of b subunit found in some F-ATPases; in other cases, there are two identical b subunits

established by specific additional proteins (Spikes et al. 2020).

V-ATPases are proton-transporting proteins that generate a lower pH inside the compartments, thus activating the hydrolytic enzymes present in them. V-ATPases are also found in the plasma membranes of a wide variety of animal cells, including certain tumor cells, where they are involved in processes such as pH *homeostasis* or metastasis. V-ATPases have also been found in plants and *fungi*. The structures of these enzymes are more complex than those of F-ATPases and even than A-ATPases, to which they are more related both structurally and phylogenetically (Grüber and Marshansky 2008; Kühlbrandt 2019). Among the functional differences of V-ATPases and other rotary ATPases, they can be regulated by reversible disassembly in V_0

ATPase, Fig. 2 Model of the structure and function of mammalian brain V-ATPase

and V₁ complexes, and by the use of isoforms of *a* subunit (Sharma et al. 2018; Wang et al. 2020).

In some anaerobic bacteria, *extremophiles* (particularly, thermophilic and *alkaliphilic*), and Archaea, the coupling ion used by F and V-types ATPases is Na⁺ instead or in addition to H⁺, and a sodium motive force (SMF) substitutes the PMF (Schlegel et al. 2012). Certain studies suggest that the Na⁺-dependent ATPases came first in terms of evolutionary history; however, some others consider them as a secondary adaptation to survival in extreme environments (Dibrova et al. 2015; Lane et al. 2010; Mulikdjanian et al. 2008).

The ABC family of proteins constitutes a large and ubiquitous superfamily that includes both

soluble and integral membrane proteins (Furuta 2021; Locher 2009; Wilkens 2015). These last ones are responsible for the ATP-powered translocation of many substrates across membranes, existing importers, and exporters. ABC transporters found in *prokaryotes* can be importers or exporters; however, eukaryotic ones are mainly dedicated exporters. Their hydrophilic nucleotide-binding domains (NBD) are highly conserved and provide the nucleotide-dependent engine that drives transport. By contrast, the transmembrane domains (TMD) that generate the translocation pathway are more variable. In importers, both domains are in separate subunits while in exporters are in a unique protein (Fig. 3). In prokaryotes, the

A

ATPase, Fig. 3 Model of the structure and function of ABC-multidrug exporters and importers *TMD* transmembrane domain, *ABC* ATP-binding cassette, *SBP* substrate-binding protein

importers provide the cell with hydrophilic nutrients, while exporters remove different xenobiotics and hydrophobic substances from the cell. The prokaryotic exporters are responsible for the efflux of drugs that cause certain *antibiotic* resistances, and the eukaryotic ones can prevent the inhibitory effect of anticancer drugs by preventing their accumulation within the tumor cells. For functioning, the importers require a substrate-binding protein (SBP).

P-ATPases are enzymes present in some biological membranes of prokaryotes and eukaryotes, which promote cations or lipid transport using the energy from ATP hydrolysis (Kühlbrandt 2004). All members of this family have certain amino acid sequence conservation, particularly the Asp residue that suffers the phosphorylation/dephosphorylation involved in the process, and is inhibited by vanadate. Some are unique polypeptides with multiple membrane-spanning regions, while others have a second subunit. Based on phylogenetic analysis, P-ATPases have been classified into five main classes named P1-P5 (Pedersen et al. 2012). This type of enzyme is widely distributed and includes representatives in animals (Na^+K^+ -ATPase, Ca^{2+} -

ATPase, Fig. 4 Model of the structure and function of the Ca^{2+} -ATPase, a P-ATPase

ATPase, H^+K^+ -ATPase), plants and fungi (plasma membrane H^+ -ATPase), and bacteria (Ag^+ , Cd^{2+} , Cu^{2+} , Hg^{2+} , or Zn^{2+} ATPases). P4-ATPases transport or flip phospholipids. Albeit their diversity in ion specificity, all P-ATPases are homologues (Fig. 4).

Basic Methodology

The main methodologies used for the studies on ATPases include crystallization and structure determination by X-ray diffraction; nuclear magnetic resonance (NMR) of particular subunits or complexes; electron and fluorescence microscopy including visualization of the rotational movement of F₁-ATPase, after attaching the rotating subunit to a *fluorescent* structure (Noji et al. 1997) and kinetic and binding studies of the enzyme activities, as well as genetic studies based on the effect of protein sequence modifications. Since the implementation of single-particle analysis of protein complexes by high-resolution cryogenic electron microscopy (cryo-EM) techniques, a revolution in the knowledge of the structure and function of rotary ATPases has taken place (Kühlbrandt 2019).

Key Research Findings

Boyer's group proposed in 1973 (Boyer et al. 1973) that the step requiring energy in the synthesis of ATP by ATP synthase was the release of the ATP molecule from the enzyme. Three years later, the binding change mechanism was proposed by this group. The first X-ray structure of an incomplete F₁ complex was published by Walker's group in 1994 (Abrahams et al. 1994). In 1997, Yoshida's group was able to record the movement of the F₁ complex during ATP hydrolysis, now including the gamma subunit (the rotating shaft of the enzyme), after attaching individual complexes to a surface and looking to a fluorescent actin filament attached to the γ subunit (Noji et al. 1997). In 2004, the mechanically-driven synthesis of ATP by the F₁ complex was also demonstrated in experiments, in which the γ subunit inserted in the F₁ complex was induced mechanically to rotate in the presence of ADP and phosphate, and ATP was afterward released to the medium, with a more complete view of the process in more recent studies (Kühlbrandt 2019). Many more research findings have been reported since the use of cryo-EM, and high-resolution structural models of different rotary ATPases from different organisms are available (Colina-Tenorio et al.

2018; Hahn et al. 2018; Nakanishi et al. 2018; Guo et al. 2019; Abbas et al. 2020; Pinke et al. 2020; Sobti et al. 2020; Sobti et al. 2021; Spikes et al. 2020; Srivastava et al. 2018; Wang et al. 2020), since the first report using these techniques on ATPases proteins by Allegretti et al. 2015.

Future Directions

Although we begin to have a good view of how ATPases work, deeper structural analyses are needed to determine the mechanisms of ions that pass through the ATPases domains and of torque generation. Comparison of the structures of ATPases of different origins should also help in determining the most relevant aspects of this issue, including the function of dimerization in mitochondrial F-ATPases. The biogenesis, assembly, and regulation of the rotary ATPases are also issues to be clarified in the next future, as some researchers are beginning to do (Miranda-Astudillo et al. 2021). Acquiring a more dynamic view of the functioning of these enzymes will have to be addressed by molecular dynamics studies based on more developed informatic systems when available. In the astrobiological field, the rising of this enzymatic activity, and the ions that could have been used by the first ATPases, in the *origin of life*, are still controversial, and thus research in this field would be of great interest.

Definition

AU stands for astronomical unit. It is the average Earth-Sun distance, corresponding to 149.6×10^6 km (or approximately 8 light-min or 100 Sun diameters). This is one of the basic units of astronomy. Other distance units (pc, kpc, etc.) are derived from it.

Definition

Autocatalysis is catalysis by one or more of the products of a reaction. Autocatalysis is often seen as the minimal requirement for the emergence of ► [life](#), as it is at the core of modern biogenetic theories based on genetic replicators, metabolic networks, and containment reproducers. Autocatalysis is one of the pathways for chiral symmetry breaking and is also responsible for the formation of patterns and ordered periodic behavior in chemical reactions. While autocatalytic phenomena have been observed in fields as diverse as cell biology and nonlinear physics, their general study is the subject of the emergent field of “Systems Chemistry.”

Overview

Autocatalytic reactions are described by the equation:

where a and p are reaction orders, P is the autocatalyst, and A is a precursor molecule. The autocatalytic reaction order p determines the “explosivity” of the product growth, which increases from parabolic ($p = \frac{1}{2}$) to exponential ($p = 1$) and hyperbolic ($p = 2$). Each type of growth has distinct evolutionary consequences. Competition between two or more autocatalysts – for a common resource constituent A – leads to coexistence (“survival of everybody”) for

parabolic, selection (“survival of the fittest”) for exponential, and fixation (“survival of the least common”) for hyperbolic growth.

Typically, the concentration-time curve of formation of an autocatalyst has a sigmoidal form (see Fig. 1), which is the result of a self-accelerating growth phase followed by deceleration due to the consumption of precursors.

Coupling of autocatalytic cycles with other reactions including autocatalytic ones can lead to oscillating behavior and spatiotemporal pattern

Autocatalysis, Fig. 1 (a) Typical sigmoidal concentration-time curve observed in many autocatalytic reactions. Initially, the reaction rate is slow, while the catalyst concentration is low. The reaction rate increases as more products are formed and then slows down when the reagents are consumed or inhibition by template takes place. The character of the growth phase can be parabolic, exponential, or hyperbolic, according to the reaction mechanism involved in the process. (b) Periodic concentration

oscillations of ferroin (Fe (II)) and ferritin (Fe (III)) complexes in Belousov-Zhabotinsky reaction. Reaction with limited diffusion creates spatial patterns as observed in this photo. (c) Scheme of a simple four-component cross-catalytic network. Precursors A and B can form two autocatalysts AB and BA or a group of cross-catalysts AA and BB . The scheme represents the reaction mechanism reported by Sievers and von Kiedrowski (1994)

formation. One example is the well-known Belousov-Zhabotinsky reaction.

Autocatalysis can be found in both catabolic reactions (e.g., hydrolysis of simple esters) and anabolic reactions (e.g., template replicators). Feedback may result from simple autocatalysis by one product, cross-catalysis between two products, or an “autocatalytic set” of molecules forming a network of mutually catalytic interactions.

Many genetic theories of the origin of life (e.g., the ► “RNA world” model) demand self-replication of nucleic acids in the absence of enzymes. Self-replication means autocatalysis plus information transfer. The latter is usually based on a templating principle according to which the product transfers its blueprint as constitutional information. It has been demonstrated using nucleic acids, peptides, and small organic molecules as templates.

Metabolic theories call for cycles that generate larger molecules from small building blocks in an anabolic direction, whereas the autocatalysis itself results from a catabolic split to yield medium-sized intermediates (as in the ► “Formose reaction”).

Autopoietic theories require self-reproduction of a container as well as the included components. Experimental examples have been found in reactions where lipid molecules forming micelles or vesicles are generated from non-lipid precursors via phase-transfer autocatalysis.

Several modern theories for the origin of (bio) molecular homochirality are supported by examples of enantioselective autocatalysis and chiral symmetry breaking.

Current research challenges in the field of Systems Chemistry are programmed design of autocatalytic systems and their integration into dynamic supersystems.

Definition

There is a remarkable gap between complex chemical systems that generate self-organizing

patterns (e.g., oscillations in Belousov-Zhabotinsky types of reactions) and the chemical self-construction that any living being achieves through its metabolism. Chemical self-organization mechanisms operate at many different levels in biological systems, but the network of continuous transformation processes underlying the constitution of an organism is something clearly distinct. The idea of a **chemical automaton** addresses precisely this issue, trying to determine what an autocatalytic reaction network requires to become an autonomous, self-producing system. So far we lack experimental evidence of chemical automata that are not living metabolic systems, but synthetic biology and current projects to fabricate artificial cells may soon provide interesting insights to this problem, which has been extensively explored theoretically in the past.

Definition

Autopoiesis is a recurrent set of component production processes that creates a physical/topological boundary, within which that set of processes is continuously realized.

History

The term was originally proposed by H. Maturana and F. Varela in the early 1970s (from Greek: *auto*, “self,” and *poiesis*, “production”) and proposed as an abstract definition of ► [life](#). According to these authors, an autopoietic system is “organized as a network of processes of production (transformation and destruction) of components which: (1) through their interactions and transformations continuously regenerate and realize the network of processes (relations) that produce them; and (2) constitute it (the machine) as a concrete unity in the space in which they (the components) exist, by specifying the topological domain of its realization as such a network.”

[Primary producer](#)

Definition

Autotroph is an organism capable of biosynthesizing all cell material from carbon dioxide as the only carbon source. With respect to energy, autotrophs can obtain it from two sources: (1) photoautotrophs from radiation (sunlight) and (2) chemolithoautotrophs from the oxidation of reduced inorganic substrates. Autotrophs are capable of growth exclusively at the expense of inorganic nutrients, and they are of vital importance in the cycling of inorganic compounds on Earth including methanogens, which produce methane from H_2 and CO_2 , and nitrifiers, which convert ammonia to nitrate. Autotrophs are the source of reduced carbon substrates for the heterotrophs. Autotrophs are key elements of the ▶ [carbon cycle](#). For this reason, autotrophic organisms are also called primary producers.

Definition

Autotrophy is a lifestyle in which inorganic compounds provide for all nutritional needs of an organism. Implicit in this definition is the capacity of an organism to derive all cell carbon from carbon dioxide. Energy can be derived from two sources: (1) Photoautotrophs are photosynthetic and obtain energy from sunlight. (2) Chemolithoautotrophs obtain energy by the oxidation of inorganic substances. Table 1 shows a general classification of organisms on the basis of carbon and energy sources.

Autotrophy, Table 1 Classification of metabolisms according to energy, reducing power, and carbon sources

Metabolism	Energy source	Reducing power	Carbon source
Chemo-litho-autotrophic	Oxidation of inorganic compounds	Inorganic compounds	CO ₂
Photo-litho-autotrophic	Visible light	Inorganic compounds	CO ₂
Photo-organo-heterotrophic	Visible light	Organic compounds	Organic compounds
Chemo-organo-heterotrophic	Oxidation of organic compounds	Organic compounds	Organic compounds

Overview

Autotrophs are capable of growth exclusively at the expense of inorganic nutrients, and they are vital in the cycling of inorganic compounds (Alberts et al. 1994; Campbell and Reece 2002). Such autotrophs not only completely satisfy their own needs for reduced carbon monomers from inorganic matter but could also feed the already existing heterotrophs. Thus, autotrophic organisms are also called primary producers. Carbon dioxide that is fixed into organic compounds as a result of autotrophic activity is available for consumption or respiration by animals or heterotrophic microorganism. The end products of respiration in heterotrophic organisms are water and carbon dioxide, and this way the carbon cycle is completed (Alberts et al. 1994; Campbell and Reece 2002). Now it is accepted that autotrophy is an extremely important process on Earth and autotrophic microorganisms, as primary producers, support the growth of non-autotrophic organisms (Maier et al. 2000).

Photoautotrophs

A large number of microorganisms, as well as the green plants, algae, and protists, are phototrophic. They use light as an energy source in the process called photosynthesis. The result of this mechanism is the generation of a proton motive force that can be used in the synthesis of ATP and the synthesis of reducing power (e.g., NADPH). Most phototrophs use energy conserved in ATP and electrons in NADPH for the assimilation of carbon dioxide as the carbon source for biosynthesis. These phototrophs are called photoautotrophs. There are also phototrophs able to use organic compounds as carbon sources with light as energy source; they are

called photoheterotrophs (Table 1) (Campbell and Reece 2002; Maier et al. 2000; Madigan et al. 2003).

Chemolithoautotrophs

In the 1880s, Sergei Winogradsky (1856–1953) proposed the concept of chemolithotrophy, the oxidation of inorganic compounds as a source of energy and electrons for autotrophic growth. Studying sulfur bacteria (*Beggiatoa* and *Thiothrix*), he concluded that these organisms obtained their carbon from CO₂ in air, and they were called autotrophs. The discovery of autotrophy in chemolithotrophic bacteria was of major significance in the advance of our understanding of cells physiology because it showed that CO₂ could be converted to organic carbon without photosynthesis. Chemolithotrophy is shown by members of both the Bacteria and Archaea domains. Chemolithoautotrophs are important in the cycling of inorganic compounds in Earth, including methanogens, which produce methane, and nitrifiers, which convert ammonia to nitrate (Madigan et al. 2003; Ehrlich 2002).

Key Research Findings

Autotrophic Pathways

Eight biochemical mechanisms are known for the autotrophic fixation of CO₂ into cell material. The pathways differ in the participating enzymes, ATP, and reducing power requirements and carbon isotope fractionation (Maier et al. 2000; Madigan et al. 2003; Berg et al. 2010).

1. The Calvin-Benson cycle, discovered in the 1950s in Melvin Calvin's lab, starts with the

condensation of a 5-C sugar (ribulose 1,5-bisphosphate) with CO_2 to yield two molecules of 3-C (3-phosphoglycerate) (Fig. 1a). From these molecules, both the initial 5-C sugar is regenerated and organic materials are biosynthesized. The cycle is operative in plastids of plants, algae, and protists, as well as in cyanobacteria, some aerobic or facultative anaerobic proteobacteria, CO-oxidizing mycobacteria, some iron- and sulfur-oxidizing

firmicutes, and green sulfur bacteria. The ability to fix carbon by this pathway is conferred by the activity of two enzymes (together with fragments of central metabolism like gluconeogenesis and the pentose phosphate pathway): ribulose 1,5-bisphosphate carboxylase-oxygenase (► [Rubisco](#)) and phosphoribulokinase (Campbell and Reece 2002; Maier et al. 2000; Madigan et al. 2003). Although Rubisco activity has been

Autotrophy, Fig. 1 The diversity of autotrophic pathways. A scheme of stoichiometric relationships in (a) the Calvin-Benson cycle, (b) the Arnon cycle, (c) the Wood-Ljungdahl pathway, (d) the hydroxypropionate bicycle, (e)

the hydroxypropionate/dicarboxylate-hydroxybutyrate cycles, and (f) the reductive glycine pathway. In each case, the identity of the net product of C fixation, the starting point of biosynthesis, is indicated

detected in some Archaea, it has not been possible to demonstrate Calvin-Benson-dependent autotrophic growth (Berg et al. 2010).

2. Several autotrophic prokaryotes that use the Calvin-Benson cycle for CO₂ fixation produce polyhedral cell inclusions called carboxysomes. Carboxysomes are made of polyhedral protein shells about 80–120 nm in diameter (Fig. 2). These compartments are surrounded by a thin membrane and consist of a tightly packed crystalline array of molecules of Rubisco (Tsai et al. 2007). Thus, the carboxysomes would be a mechanism to increase the amount of Rubisco in the cell to allow for higher rates of CO₂ fixation. Carboxysomes have been found in obligately chemolithotrophic sulfur-oxidizing bacteria, nitrifying bacteria, cyanobacteria, and prochlorophytes. They are not present in facultative autotrophs like purple anoxygenic phototrophs, despite the fact that when these organisms grow as photoautotrophs, they use the Calvin-Benson cycle to fix CO₂. Thus, the carboxysome may be an evolutionary adaptation to life under strictly autotrophic conditions (Madigan et al. 2003).
3. In the green sulfur bacterium *Chlorobium*, CO₂ fixation occurs by a reversal (or reductive) citric acid cycle, also known as the Arnon cycle (Madigan et al. 2003; Evans et al. 1966). This is the analogue of a Krebs cycle operating in reverse mode (Fig. 1b). Since the Arnon cycle involves some enzymes (e.g., the carboxylating and reducing steps) that are inhibited by oxygen, this pathway is only found in microorganisms growing under anaerobic conditions. These include some proteobacteria, green sulfur bacteria, and microaerophilic bacteria like *Aquifex* (Maier et al. 2000; Madigan et al. 2003).
4. In some Gram-positive bacteria and methanogenic archaea, the ability to synthesize acetyl-CoA from CO and/or CO₂, the Wood-Ljungdahl pathway, was identified (Madigan et al. 2003; Ljungdahl et al. 1965). One CO₂ molecule is reduced to CO and another one to a methyl group (attached to a cofactor). Then, acetyl-CoA is synthesized from CO and the methyl group (Fig. 1c). The key enzymes of this pathway are inhibited by oxygen; thus it is restricted to obligate anaerobic microorganisms. These include some proteobacteria, planctomycetes, spirochaetes, and archaea (Maier et al. 2000; Madigan et al. 2003; Berg et al. 2010).
5. The 3-hydroxypropionate bicycle is present in some green non-sulfur phototrophic bacteria like *Chloroflexus* (Herter et al. 2002). A succinyl-CoA molecule is synthesized from acetyl-CoA and two bicarbonate molecules (Fig. 1d). Although the same intermediates as

Autotrophy, Fig. 2 (a) A thin-section electron micrograph of *Halothiobacillus neapolitanus* cells with carboxysomes inside. In one of the cells shown, arrows highlight the visible carboxysomes. (b) A negatively stained image of intact carboxysomes isolated from

H. neapolitanus. The features visualized arise from the distribution of stain around proteins forming the shell as well as around the Rubisco molecules that fill the carboxysome interior. Scale bars indicate 100 nm (Figure from Tsai et al. (2007))

the hydroxypropionate-hydroxybutyrate cycle (see below) are used, most of the participating enzymes are different. The final product of the cycle is glyoxylate. Its assimilation requires a second metabolic cycle. This pathway is restricted to the family *Chloroflexaceae* and might represent an early attempt of autotrophy in anoxygenic phototrophs (Maier et al. 2000; Madigan et al. 2003).

6. The hydroxypropionate-hydroxybutyrate cycle occurs in some aerobic archaea, like *Sulfolobus*. Albeit this pathway is formally the same as the 3-hydroxypropionate bicycle, the non-homologous participating enzymes indicate that both pathways evolved independently in a remarkable case of evolutionary convergence in metabolism (Berg et al. 2010) (Fig. 1e).
7. The dicarboxylate-hydroxybutyrate cycle occurs in some anaerobic archaea like the Thermoproteales and Desulfurococcales. The pathway can be divided into two parts (Fig. 1e): (1) one acetyl-CoA, one CO₂, and one bicarbonate are converted into succinyl-CoA; (2) this C4 molecule is transformed into two molecules of acetyl-CoA (one serves as biosynthetic precursor, the other as acceptor of the cycle) (Berg et al. 2010).
8. The reductive glycine pathway (rGly) was predicted by the late Arren Bar-Even and collaborators, and demonstrated in the autotrophically grown sulfate-reducing bacterium *Desulfovibrio desulfuricans* (Sánchez-Andrea et al. 2020). As shown in Fig. 1f, in the first step, CO₂ is reduced to formate, which is reduced and condensed with a second CO₂ and ammonia to generate the amino acid glycine. Finally, glycine is further reduced to produce acetyl-CoA. Since the immediate precursor of acetyl-CoA is acetyl phosphate, ATP may be produced. The rGly is considered one of the most energy-efficient autotrophic pathways. Although its real impact on the global carbon cycle is as yet unknown, preliminary phylogenomic analyses indicate that it may have a wide distribution in bacteria.
9. In 2018, the reverse operation of a conventional oxidative TCA cycle was independently described in two strictly anaerobic

chemolithotrophs: the *Thermosulfidibacter takaii* (Nunoura et al. 2018) and *Desulfurella acetivorans* (Mall et al. 2018). Although the stoichiometric balance is represented by Fig. 1b, this is not an analogous reverse TCA cycle, as the Arnon cycle, but the thermodynamic reversion of a TCA cycle using the same enzyme repertoire as in the oxidative mode. Although the ancestral character of this metabolic mode, as suggested by Nunoura et al. (2018), is doubtful, it really represents a challenge for metabolic prediction solely based on bioinformatic analyses of environmental metagenomes, as pointed out by Mall et al. (2018). This is because the same genotype (the Krebs cycle enzyme repertoire) gives support to both phenotypes, heterotrophic (oxidative mode) and autotrophic (reductive mode), depending on the environmental conditions (for instance, CO₂ concentration, as shown by Steffens et al. 2021).

Applications

Ecology

Autotrophs are present in all ecosystems. They take energy from the environment in the form of sunlight or inorganic chemicals and use it to create energy-rich molecules such as carbohydrates. Thus, they meet their requirements easily and can be constitutive around the world. Moreover, autotrophic organisms are primary producers and, as a consequence, they are at the pyramidal base of the ecosystems. Thus, heterotrophs depend on autotrophs for the energy and raw materials they need (Maier et al. 2000). On the other hand, autotrophs, as a consequence of their poor requirements, have greater adaptability; thus, they are especially important in oligotrophic environments, like oligotrophic lakes, glaciers and ice, acid waters, geothermal systems, etc.

Rio Tinto (Huelva, Southwestern Spain) is an example of an environment dominated by autotrophic bacteria. This ecosystem is of great interest to astrobiology (Fig. 3). It is an extreme environment with a rather constant acidic pH along the entire river and a high concentration of heavy metals. The extreme conditions of the Tinto

A

Autotrophy, Fig. 3 Rio Tinto is an example of an ecosystem dominated by autotrophic microorganisms. The Iberian Pyritic Belt (IPB) is a 250-km long geological entity located in the southern Portuguese geotectonic zone of the Iberian Peninsula. Massive bodies of iron and copper sulfides constitute the main mineral ores. When part of the IPB was exposed to the atmosphere, autotrophic iron-oxidizing bacteria, giving rise to a river of extremely acidic water with an intense red color due to the resulting

ferric. This extreme site presents a high microbial diversity, especially of photosynthetic eukaryotes (mainly algae). The central role of chemolithoautotrophic organisms and the high photosynthetic biomass make Rio Tinto an excellent model for the study of autotrophy. The spectacular contrast between the green of the algae and the intense red of the water can be observed at numerous places of the river

ecosystem are generated by the metabolic activity of chemolithotrophic microorganisms thriving in the rich complex sulfides of the Iberian Pyrite Belt. In this system, more than 70% of the cells are affiliated to autotrophic bacteria (iron-oxidizing bacteria), with only a minor fraction corresponding to heterotrophic. The special interest shows also autotrophic microalgae, present in the river, primary producer, together with iron-oxidizing bacteria, of the system (González-Toril et al. 2003).

Autotrophy and Early Evolution of Life

The autotrophic metabolism has emerged independently several times during evolution, that is, it is a polyphyletic trait (Berg et al. 2010; Pereto et al. 1999). The Calvin-Benson cycle seems idiosyncratic to bacteria, whereas the Arnon cycle and the Wood-Ljungdahl pathway show a wider phylogenetic distribution. The different versions of the hydroxypropionate pathway likely emerged independently (Berg et al. 2010). At this moment, phylogenetic analysis of the participating enzymes does not allow us to infer which one is the older pathway.

Mainstream hypothesis on the [origin of life](#) postulates that the first prokaryotes were anaerobic heterotrophs, for example, fermenters. In the beginning, they may have fed on externally available abiotic organic molecules, either synthesized on Earth or delivered by extraterrestrial bodies. It is generally supposed that autotrophic metabolism emerged later.

Whether the first autotrophs were chemosynthetic or photosynthetic is a matter of debate. One school of thought favors chemosynthetic autotrophs in the form of methanogens, which formed methane. Microorganisms (methanogenic archaea) with such metabolism exist today, and they are strict anaerobes. The other school of thought favors photosynthetic prokaryotes in the bacterial domain as the first autotrophs. This notion is supported by the existence of the Warrawoona stromatolites, which are around 3.5 billion years old. Those microfossils have been interpreted, on the basis of comparison with modern counterparts, to have been formed by cyanobacteria. However, modern cyanobacteria are aerobes. Because the primordial atmosphere at this

time is thought to have been almost free of oxygen, the emergence of anaerobic photosynthetic bacteria, of which modern purple and green bacteria must be a counterpart, must have preceded that of cyanobacteria (Campbell and Reece 2002).

On the other hand, in 1988, Wächtershäuser proposed the surface metabolism theory for the origin of life (Wächtershäuser 1988). According to it, life arose as a form of autocatalytic two-dimensional chemolithotrophic metabolism on a pyrite surface, using the energy and electrons of the anaerobic synthesis of FeS₂ (pyrite) from FeS and H₂S. According to this proposal, the ancestral carbon fixation pathway would be a primitive version of the Arnon cycle (Wächtershäuser 1990). The Wood-Ljungdahl pathway has also been proposed as a candidate of the older autotrophic mechanism (Pereto et al. 1999; Russell and Martin 2004). The lack of experimental evidences is the weaker aspect of the autotrophic hypothesis on the origin of life.

Future Directions

Engineering Autotrophy

With the aim to moderate carbon emissions and the building of a more sustainable circular economy, research on the enzyme mechanisms of CO₂ fixation and the development of new-to-nature carboxylases and synthetic autotrophic pathways has been stimulated. For instance, a fully artificial carbon fixation cycle was obtained by combining enzymes from nine different organisms of all three domains of life using enzyme and metabolic engineering tools (Schwander et al. 2016). On the other hand, by metabolic engineering and directed evolution, it was possible to convert a heterotrophic organism like *Escherichia coli* in a full-fledged autotrophic system able to build all the biomass with CO₂ as a sole carbon source (Gleizer et al. 2019). Finally, the endogenous, hidden capacity of heterotrophic metabolic networks to operate in autotrophic mode has also been discovered (Satanowski et al. 2020). All these pioneering works explore a diversity of natural and artificial

carbon fixation pathways with potential applications in biocatalysis, biotechnology, and artificial photosynthesis (Bernhardsgrütter et al. 2021).

Meudon, France

Definition

A background is a diffuse radiation field originating from no specific location in the sky. When observing a given field, it is that part of the signal which is not due to the objects of interest and comes from extended or unresolved sources behind them. At millimeter wavelengths, the microwave background, the fossil emission from the Big Bang, is present in any direction of the sky. By extension, the molecular glow or the thermal infrared emission from the atmosphere as well as from the telescope that is superimposed on the astronomical signal is also called background.

Bacteria

Definition

Bacteria are a large group of single-celled phylogenetically related prokaryotes distinct from ► [Archaea](#). Bacteria have a wide range of shapes, ranging from spheres to rods and spirals. They are ubiquitous, growing in soil, water, extreme environments, and deep in the Earth's crust (Vreeland et al. [2000](#); Wanger et al. [2008](#)). There are typically 40 million bacterial cells in a gram of soil and a million bacterial cells in a milliliter of fresh water. There are approximately 5×10^{30} bacteria on Earth, forming much of the world's biomass (Whitman et al. [1998](#)). Bacteria are vital in recycling nutrients and important elements of the geobiological cycles. Most have not been characterized, and only about half of the phyla of bacteria have species that can be grown in the laboratory.

Once regarded as plants constituting the class Schizomycetes, bacteria are now classified as prokaryotes. Unlike the cells of animals and other eukaryotes, bacterial cells do not contain a nucleus and rarely harbor membrane-bound organelles. Although the term bacteria traditionally included all prokaryotes, the scientific classification changed after the discovery in the 1970s that prokaryotes consist of two very different groups of organisms (domains) that evolved independently from an ancient ► [common ancestor](#). These evolutionary domains are called bacteria and ► [Archaea](#).

History

Bacteria were first observed by Antonie van Leeuwenhoek in the seventeenth century, using a single-lens microscope of his own design (Porter 1976). He called them “animalcules” and published his observations in a series of letters to the Royal Society (van Leeuwenhoek 1684). The name bacterium was introduced much later, by Christian Gottfried Ehrenberg in 1838.

Louis Pasteur demonstrated in the mid-eighteenth century that ► [fermentation](#) is caused by the growth of microorganisms and that this growth is not due to spontaneous generation. Along with his contemporary, Robert Koch, Pasteur was an early advocate of the germ theory of disease. In his research into tuberculosis, Koch finally proved the germ theory, for which he was awarded a Nobel Prize in 1905. In Koch’s postulates, he set out criteria to test if an organism is the cause of a disease, and these postulates are still used today. A major step in the study of bacteria was the development, in the middle of the last century, of molecular biology techniques with which much was learned about their biochemistry and genetics. In 1977, Carl Woese (Woese and Fox 1977) made an important breakthrough in our knowledge of evolution, when, in comparing the sequences of 16 S ribosomal RNA genes, he observed that a group of prokaryotic organisms, Archaea, have a separate line of evolutionary descent from that of bacteria (Woese et al. 1990).

Overview

Bacteria is one of the two types of prokaryotic organisms, the other is Archaea. Eukaryotic cells actually represent a consortium of cells including a host or nucleus cytoplasm and the endosymbiotic organules: mitochondria and chloroplast, both of bacterial origin (Dyall et al. 2004). The separation between bacteria and Archaea is largely derived from molecular biology studies, mostly on ► [ribosome](#) structure and components (proteins and ribosomal RNA) and ► [transcription](#) machinery (RNA polymerase). Bacteria indeed have representatives carrying out most

known metabolic pathways and driving the functioning of most ecosystems. The only known metabolic strategy that is not found in bacteria is the archaeal methanogenesis (DeLong and Pace 2001). Bacteria can actually close all biogeochemical cycles on their own, so that a uniquely bacterial biosphere can be envisioned. This is not true of either eukaryotes or Archaea (at least with the admittedly limited knowledge that we have about this group).

The classification of bacteria has undergone frequent changes in the last few years and is subject to continuous controversy as is their relationship with the other major cellular types. The widely accepted classification scheme is based on the 16S rRNA sequence comparisons. The most recent classification schemes describe the following groups of Bacteria: ► [Proteobacteria](#) (*Alpha*-, *Beta*-, *Gamma*-, *Delta*-, *Epsilonproteobacteria*), *Acidobacteria*, *Aquificae*, *Chlorobi*, *Bacteroidetes*, *Chlamydiae/Verrucomicrobia*, *Planctomycetes*, *Spirochaetes*, *Actinobacteria*, *Chloroflexi*, *Cyanobacteria*, *Firmicutes*, *Tenericutes*, *Fusobacteria*, *Synergistetes*, *Thermotogae*, and *Deinococcus/Thermus*.

Some of these groups are extremely diverse in metabolism, while others are very restricted. However, the availability of cultivated species, properly studied for their physiology, is very uneven (Rappé and Giovannoni 2003). At least in some cases, this might influence our perception of their true diversity. Cellular organization and structure is also highly variable although most bacteria have a rigid cell wall consisting of one single group of tridimensional polymers, mureins, or peptidoglycans. Some bacteria, gram-negative bacteria, also have an extra membrane outside the rigid polymer that provides a second permeability barrier. The outer membranes of the gram-negative bacteria have a very characteristic structure with a long chain polysaccharide facing the extracellular environment and providing a hydrophilic envelope. Some groups of gram-positive bacteria also have an outer membrane, very different chemically and more interlinked to the underlying polymer. Sometimes these gram-positive bacteria outer membranes are also quite hydrophobic. Finally some bacteria have

glycoprotein S layers as rigid envelopes and some have no rigid envelope at all.

► **Motility** is common in bacteria and is achieved by a characteristic structure, the bacterial flagellum (Kojima and Blair 2004). This nanorotor is unique and different structurally and phylogenetically from its archaeal and eukaryotic counterparts. The archaeal flagellum is more similar to a different bacterial structure that is actually involved in some types of bacterial motility by gliding. In spirochetes, the flexing spiral body rotation is achieved by inward directed flagella that are coiled over the cell. Some bacteria have other types of motility such as gliding over surfaces. This capacity is particularly efficient in social bacteria that move in multicellular consortia. This is the case for myxobacteria (a group within the deltaproteobacteria).

Although no organelles have been described in bacteria, there are examples of fairly complex cellular structures, including the presence of nuclear membranes, previously considered unique to eukaryotes (Fuerst 2005). Other cellular organelle-like structures (Yeates et al. 2008) are magnetosomes, peroxisomes, gas vesicles, and storage granules. Cell division in bacteria is achieved by a cross-divisional cell wall septum, a constriction encompassing all the cell envelope layers. Although there is no mechanical cell machinery such as the mitotic apparatus of eukaryotes, bacteria have proteins homologous to actin that can produce mechanical modification of cell morphology (Shih and Rothfield 2006).

Cell shape and size varies widely in bacteria. However, most bacterial cells conform to relatively simple geometric shapes based in the cylinder (rod), sphere (coccus), or the spiral coil (spirillum) (Young 2006). Cells can vary in size from fractions of a micron to many hundreds of microns in giant bacteria such as *Thiomargarita* or *Epulopiscium* (Schulz and Jorgensen 2001). Bacterial size is limited by their osmotrophic feeding, that is, their need to transport all nutrients across the membrane. This is only efficient as long as a high surface/volume ratio is maintained.

Bacterial reproduction is asexual, by clonal duplication of the cell, and originates large populations of clonal descent. This has been used

for pure culture isolation and study since the origins of microbiology. However, bacteria have sex, often referred to as horizontal gene transfer or lateral gene transfer. The impact of this genetic exchange that has no part in reproduction is considered fundamental in the evolution of bacteria. The absence of meiotic processes and zygote formation leads to the possibility of genetic exchange among very different partners. In this way, the barriers to genetic recombination in bacteria are very leaky, if present at all. The impact of horizontal gene transfer in the evolution of the prokaryotic (bacterial and archaeal) world is still a matter of controversy, but some authors consider that a biologically consistent tree of life based on evolutionary relationships could simply be a human fabrication.

Bacteriorhodopsin

Ricardo Amils
Departamento de Biología Molecular, Madrid,
Spain

Definition

Bacteriorhodopsin is a membrane protein that captures radiation energy which is used to create a proton gradient. It can be found mainly in Haloarchaea. Bacteriorhodopsin is a membrane protein usually found in two-dimensional crystalline patches known as purple membrane. The repeating element of the hexagonal lattice is composed of three identical protein chains, each rotated by 120° relative to the others. Each chain has seven transmembrane alpha helices and contains one molecule of retinal buried deep within. It is the retinal molecule that changes its conformation when absorbing a photon, resulting in a conformational change of the bacteriorhodopsin promoting the proton pumping action. It can be considered the simplest photosynthetic system known. All other phototrophic systems (bacteria, algae, chloroplasts) use chlorophylls instead of bacteriorhodopsin to generate proton gradients.

Baly's Experiment

Stéphane Tirard
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Faculté des Sciences et
des Techniques de Nantes, Nantes, France

Definition

Regarding origin of life, Baly's experiment (1922) is one of the most emblematic organic chemistry experiments of the beginning of the twentieth century (Baly 1871–1948). It has demonstrated that ultraviolet light could act on a solution of water, carbon dioxide, and ammonia and produce a lot of organic compounds, such as sugars and amino acids.

J.B.S. Haldane quoted these experiments in his famous text in 1929; for him, this was a chemical proof of the possibility of a link between mineral and organic chemistry in the prebiotic soup.

Banded Iron Formation

A. M. Mloszewski, Rasmus Haugaard,
Ernesto Pecoits and Kurt O. Konhauser
Department of Earth and Atmospheric Sciences,
University of Alberta, Edmonton, AB, Canada

Keywords

Geobiology · Precambrian · Iron oxides · Chert

Synonyms

BIF; Itabirite; Taconite

oxides, carbonates, and/or silicates, typically containing 20–40% iron and 40–50% silica (James 1954; Trendall 2002; Klein 2005) (Fig. 1).

Definition

A lithological term applied to a thinly bedded or laminated chemical sedimentary rock consisting of successive layers of fine-grained quartz, iron

Overview

Banded iron formations (BIFs) comprise the largest iron resource on Earth. They formed throughout much of the Precambrian (~3800–543 Ma),

Banded Iron Formation, Fig. 1 (a) Outcrop photograph of Algoma-type BIF with layers of magnetite BIF interbedded with felsic volcanoclastic rocks from the 2.9 Ga Itilliarsuk BIF, West Greenland (Haugaard et al. 2013); (b) outcrop photograph of weakly folded magnetite-quartz BIF from the ca. 2.85 Ga Central Slave Cover Group, Slave Craton, Northwest Territories, Canada (Haugaard et al. 2016a). *Brownish* bands are secondary

iron oxides and iron oxyhydroxides; and (c) a pristine BIF core sample from the Joffre Member, Brockman Iron Formation, Hamersley Province, West Australia. Black mesobands are composed mostly of dense magnetite, red micro- and mesobands are composed of chert + hematite, and gray micro- and mesobands are composed of chert + magnetite + Fe-rich carbonate (Haugaard et al. 2016b) (All photos courtesy of Rasmus Haugaard)

reaching their maximum abundance between 2700 and 2400 Ma ago. Numerous examples can be found on almost every continent. Their deposition has been linked to significant compositional changes in the Earth's atmosphere and hydrosphere and possibly even to the diversification of the biosphere.

BIF has been classified on the basis of mineralogy, tectonic setting, and depositional environment (Trendall 2002). The main iron mineral phases were used to define four "iron formation facies": oxide, silicate, carbonate, and sulfide. The dominant minerals, in their least metamorphosed state, are hematite [$\text{Fe}_2^{3+}\text{O}_3$] and magnetite [$\text{Fe}^{2+}\text{Fe}^{3+}\text{O}_4$] in the oxide facies, greenalite [$(\text{Fe}^{2+}\text{Mg})_6\text{Si}_4\text{O}_{10}(\text{OH})_8$] and minnesotaite [$(\text{Fe}^{2+}\text{Mg})_3\text{Si}_4\text{O}_{10}(\text{OH})_2$] in the silicate facies, siderite [$\text{Fe}^{2+}(\text{CO}_3)_2$] and ankerite [$\text{CaFe}^{2+}(\text{CO}_3)_2$] in the carbonate facies, and pyrite [Fe^{2+}S_2] in the sulfide facies (Klein 2005). Today, sulfide-facies iron formations (i.e., pyritic carbonaceous shale or slate) are no longer classified as BIF as they represent rock types that were deposited in different environments and developed in sedimentary successions of different ages without systematic association with BIF.

In terms of their size and lithological associations, BIF are subdivided into Algoma and Superior types. Algoma-type BIFs are comparatively small, with lateral extents rarely exceeding 10 km, thicknesses ranging from 10 to 100 m, and primary iron contents typically less than 10^{10} t (e.g., Condie 1981). They are associated with volcanogenic complexes and are inferred to have formed close to volcanic centers such as hydrothermal vents, back-arc basins, and intracontinental rift zones. By comparison, Superior-type BIFs are hundreds of meters thick, have areal extents to the order of 10^5 km², and have total primary iron contents that exceed 10^{13} t. They are typically associated with sedimentary lithologies (dolomite, quartzites, and shales) and are inferred to have been deposited on the continental shelves and slopes of passive margins (Simonson 1985). Though the water depth of deposition is still poorly constrained, the absence of wave- and current-generated features suggests a minimum water depth of ~200 m (Trendall 2002).

Banding in BIF is observed on a wide range of scales, from coarse meter-thick macrobands and centimeter-thick mesobands to millimeter- and submillimeter-scale bands. Among the latter is a wide variety of varve-like repetitive laminae, known as microbands, which may represent annual deposits (Trendall and Blockley 1970). Some Proterozoic iron formations are also found to contain iron granules, oolites, and other fragments embedded in a silica matrix (e.g., in the Lake Superior Region and the Labrador Trough, Canada; Nabberu Basin, Australia; Klein 2005). This granular variety, called granular iron formation, possesses clear detrital textures and is thought to represent eroded and redeposited fragments of preexisting BIF (Trendall 2002).

A third type of BIF, the younger (750–560 Ma) Rapitan type, is a special case in that it is linked to global glaciations ("▶ snowball Earth" events). The isolation of the oceans from the atmosphere by worldwide glacial ice cover led to ocean stagnation and buildup of dissolved, hydrothermally sourced Fe^{2+} . As the ice melted and ocean circulation reestablished itself, the iron became oxidized and formed a suite of iron formations in the oxic zone of upwelling areas (Klein 2005).

Most Eo- and Mesoarchean BIFs belong to the Algoma-type and are associated with granite-greenstone belts (volcano-sedimentary sequences). They are found in the North Atlantic Craton (Northern Labrador, southwestern Greenland), Guiana Shield (Venezuela, Guyana), Kaapvaal Craton (South Africa and Swaziland), Liberian Shield (Sierra Leone, Guinea, Liberia, and Ivory Coast), and Yilgarn Craton (Western Australia). Neoarchean to Proterozoic BIFs are mostly of the Superior type and are found in the Pilbara Craton (Hamersley Group, Western Australia), Kalahari Craton (Transvaal Supergroup, South Africa), São Francisco Craton (Quadrilátero Ferrífero), and the Superior Province (Labrador Trough and Lake Superior Regions, Canada/USA) (Trendall 2002; Klein 2005). Major deposits of the Rapitan type include the Rapitan Group in northern Canada and those in the Urucum district of Brazil (Klein 2005).

Key Research Findings

BIF Composition

Iron formations can retain the chemical signatures of the seawater from which they precipitated provided that postdepositional element mobility was minimal and may therefore be used as potential proxies for ancient seawater composition through time. Rare-earth element and yttrium (REE + Y) profiles are extensively used to determine the origin of iron formations. Two aspects of the deviation of BIF REE + Y profiles from that of modern seawater, the Eu and Ce anomalies of shale-normalized profiles, provide key information about their depositional environments (Fig. 2).

BIFs typically display positive Eu enrichments which are thought to reflect the relative influence of hydrothermal fluids on the seawater REE load at the time of deposition (Derry and Jacobsen 1990). The more pronounced Eu anomalies of

Algoma-type BIFs compared to their Superior-type counterparts suggest a higher hydrothermal component in the former due to a higher input of high-temperature hydrothermal fluids ($>250^{\circ}\text{C}$) to Archean seawater caused by a hotter mantle (Arndt 1991). The redox-sensitive element Ce is used as a proxy for the redox state of ancient seawater. Modern oxygenated seawater has a negative Ce anomaly due to oxidation of soluble Ce^{+3} to insoluble Ce^{+4} while the lack of Ce anomalies in Archean and early Paleoproterozoic BIF REE + Y profiles suggests that they were instead precipitated from anoxic seawater (e.g., Alexander et al. 2008 and references therein). Negligible fractionation of REE + Y during the initial precipitation of the precursor BIF iron oxyhydroxide minerals and their ability to withstand metamorphic conditions of up to amphibolite facies (Bau 1993) make these elements an invaluable tool for deciphering the evolution of ancient seawater conditions.

Banded Iron Formation, Fig. 2 Typical REE + Y distribution in BIF showing Eu and Ce anomalies as depicted by average values of BIF from the ca. 3700 Ga-old Isua Supracrustal Belt (southern West Greenland), compared to the average REE + Y signature of high-temperature hydrothermal fluids and average Pacific seawater (Graph modified after Alexander et al. (2008); see references therein)

To better understand the change in seawater chemistry through time and the effects of nutrient limitations on early life, recent studies derived ancient seawater composition by applying laboratory-derived partitioning coefficients between trace elements in seawater and iron oxyhydroxide particles to the absolute concentrations of these elements in BIF (P, Bjerrum and Canfield 2002; Ni, Konhauser et al. 2009; Zn, Robbins et al. 2013). Because the partitioning of P onto iron oxyhydroxides occurs in a predictable way, Bjerrum and Canfield (2002) used BIF to infer P concentrations in ancient seawater and its availability to ancient organisms. Konhauser et al. (2009) showed that Ni concentrations through time have changed drastically, with concentrations reaching up to 400 nM in the Archean (compared to an average 9 nM in modern seawater) due to an abundance of Ni-rich ultramafic rocks produced by a hotter mantle. Based on the Zn concentrations in BIF of various ages (an essential metal in the metabolism of eukaryotes), Robbins et al. (2013) suggested that Zn concentrations in seawater have remained constant through time, contrary to previously accepted ideas (e.g., Saito et al. 2003), forcing a reassessment of the influence of this metal on the timing of eukaryote evolution. Future studies of this kind on other bioessential trace metals will advance our understanding of the timing and evolution of ancient microbial metabolisms.

Yet another tool used to understand BIF genesis and the environmental conditions under which they precipitated is stable isotopes. The main traditional stable isotopes used in BIF studies are carbon ($\delta^{13}\text{C}$) and oxygen ($\delta^{18}\text{O}$) while non-traditional isotopes include iron ($\delta^{56}\text{Fe}$), silicon ($\delta^{30}\text{Si}$), and most recently, chromium ($\delta^{53}\text{Cr}$), uranium ($\delta^{238}\text{U}$), and germanium ($\delta^{74}\text{Ge}$). Carbon isotopes are primarily used as a means of understanding the genesis of iron formations. Because the organic carbon fraction in BIF is so small (typically <0.5 wt.%; Gole and Klein 1981), carbon-isotope studies tend to focus instead on the carbonate mineral fraction. The $\delta^{13}\text{C}$ signature in BIF is typically light, ranging from +2.4‰ to −20.0‰ (Johnson et al. 2008). While one school of thought interprets this light signature as evidence

of the direct carbonate precipitation from an iron-rich, carbon-isotope-stratified water column with respect to dissolved inorganic carbon (e.g., Beukes and Klein 1990), petrographic evidence suggests that much of the carbonate mineral fraction in BIF is secondary, having grown during diagenesis (e.g., Ayres 1972). More widely accepted opinions involve microbially mediated precipitation of carbonate during burial diagenesis, including carbonate precipitation through microbially mediated remineralization of (naturally isotopically light) organic matter or due to the reduction of ferric iron and precipitation of carbonate minerals by means of the bacterial oxidation of methane (see Bekker et al. 2010; Konhauser et al. 2017 and references therein).

The oxygen isotope ($\delta^{18}\text{O}$) composition of cherts in BIF is often used as a paleotemperature proxy of the seawater from which they precipitated because the oxygen isotope fractionation between silica and seawater is thought to be temperature dependent. Knauth and Lowe (2003) interpreted the depleted $\delta^{18}\text{O}$ composition of synsedimentary to very early diagenetic cherts in >3.2 Ga-old BIF (Barberton greenstone belt, South Africa) as indicative of high ocean temperature values (55–85 °C). This evidence was later corroborated by $\delta^{18}\text{O}$ data from an extensive dataset of Archean to Phanerozoic cherts, proposing that sea surface temperatures decreased drastically from about 70 °C 3500 Ma ago to about 20 °C 800 Ma ago (Robert and Chaussidon 2006). However, caution must be exercised when deriving paleo-seawater temperatures in BIF whose origin is associated with syn-depositional hydrothermal alteration (e.g., BIF older than 3500 Ma), since the derived temperatures will instead reflect local mixing conditions of hydrothermal fluids with overlying seawater.

The study of iron isotopes ($\delta^{56}\text{Fe}$) in BIF has gained momentum in recent years (e.g., Dauphas et al. 2004; Johnson et al. 2008; Haugaard et al. 2016b). While the trace element distribution in BIF will be influenced by postdepositional processes such as recrystallization and metasomatism, the iron isotope system has been known to retain its premetamorphic signature despite such conditions (e.g., Dauphas et al. 2004). Iron isotope values in BIF span the entire natural range

(−2.5‰ to +1.0‰), in contrast to the near-constant $\delta^{56}\text{Fe}$ of igneous rocks (~0‰) and other sedimentary rock types. They reflect a combination of three main processes: (a) mineral-specific equilibrium fractionation, (b) variation in the composition of fluids from which they precipitated, and (c) the effects of bacterial Fe metabolic processing (Johnson et al. 2003). Therefore, there are two important applications of $\delta^{56}\text{Fe}$ in BIF: to provide information on the abiotic and biogenic controls on ancient redox processes in the early oceans and to determine the origins for heavily metamorphosed rocks.

The $\delta^{30}\text{Si}$ compositions of early diagenetic cherts in BIF are often used to decipher the genetic processes involved in their deposition and infer the ambient surface conditions on early Earth (e.g., Andre et al. 2006). Typical compositions which range from −2.5‰ to −0.5‰ reflect relative inputs by hydrothermal (negative $\delta^{30}\text{Si}$, e.g., Andre et al. 2006) and continental (positive $\delta^{30}\text{Si}$, e.g. van den Boorn et al. 2010) sources into the depositional basin. A predominantly hydrothermal silica source can manifest itself as correlations in band-scale variations of Fe and Si isotopes, reflecting the dynamics of the hydrothermal discharge (e.g., ca. 2700 Ma-old Wanderer BIF, Zimbabwe; Steinhöfel et al. 2009). However, some of the well-studied Superior-type BIFs whose silica precipitated from a well-mixed water column far away from hydrothermal vents and continental drainage (e.g., on an isolated continental shelf platform) show a uniform $\delta^{30}\text{Si}$ composition within a single locality (e.g., the ca. 2500 Ma-old Transvaal BIF, South Africa, and Hamersley, Western Australia).

Analytical advances in stable isotope geochemistry have only recently allowed for high-precision measurements of trace element isotopes such as Cr, U, and Ge in BIF. Chromium isotope ($\delta^{53}\text{Cr}$) compositions in BIF can be used to investigate the oxygenation of the ancient atmosphere, where oxidative weathering will oxidize Cr(III) on land to the more mobile Cr(VI) which becomes enriched in surface seawater (e.g., Frei et al. 2009). It has been recently found that $\delta^{238}\text{U}$ in BIF and other marine sediments fractionate differently under oxic and suboxic to euxinic

conditions, making it another novel geochemical tracer of the Earth's redox evolution (Weyer et al. 2008). Germanium in the oceans has a short residence time (about 10,000 years). As Ge/Si ratios in seawater appear to vary in response to climate, the $\delta^{74}\text{Ge}$ composition of BIF and other marine sediments may offer new insight into the Earth's climate history (Rouxel et al. 2006).

Controls on BIF Deposition

Because the Fe contents of larger BIF are upward of 10^{13} ton, the potential Fe source must be capable of supplying these vast quantities. A widely accepted idea stems from classical BIF studies by Cloud (1973) and Holland (1973) which established that the major components (Fe and Si) in these rocks were derived from seawater. Additionally, certain aspects of the typical REE content in BIF led to the conclusion that these components were initially hydrothermally sourced and later mixed with overlying seawater (e.g., Graf 1978). The characteristic positive Eu anomalies found in BIF, a trait shared by modern hydrothermal vent fluids, are thought to indicate a strong influence of hydrothermal fluids on the BIF REE load and, by extension, Fe (Derry and Jacobsen 1990). This contrasting behavior of Eu to neighboring REE is thought to be related to the reduction of Eu^{3+} in hydrothermal solutions characterized by high temperatures (>250 °C) and low oxidation-reduction potentials. The generally positive, mantle-like ϵNd values in BIF (where the ϵNd notation defines the departure of $^{143}\text{Nd}/^{144}\text{Nd}$ from the Chondritic Uniform Reservoir evolution line), which contrast with the negative ϵNd values of seawater, support the idea that a large part of the Fe in BIF had been sourced from ancient submarine hydrothermal systems (Jacobsen and Pimentel-Klose 1988).

Our knowledge of the other major component in BIF, silica, begins with the understanding that Precambrian seawater was likely close to supersaturation with respect to amorphous silica until the evolution of organisms which incorporate silica in their skeletons, such as diatoms and radiolarians. The main sources of Si to the oceans are hydrothermal fluids and continental runoff, which have compositionally distinct Ge/Si ratios that can

be used to identify the origin of the silica in BIF. Hamade et al. (2003) established, using the Ge/Si ratios of chert bands in ca. 2500 Ma BIF of the Dales Gorge Member (Hamersley Basin, Western Australia), that most of the silica in BIF was continentally derived. Frei and Polat (2007) and Haugaard et al. 2017 later confirmed that this was also true for Algoma-type BIFs, proposing that the spread in Ge/Si ratios observed in both the ca. 3800 Ma-old Isua Supracrustal Belt and the ca. 2600 Ma-old BIF of the Slave craton (northwestern Canada) was due to the interaction of hydrothermally iron-fertilized bottom waters with silica-rich surface seawaters derived from pre-4000 Ma-old mafic land masses. Silicon isotopes have added some complexity to the issue of source since they show a perceptible hydrothermal signature in some BIFs (e.g., Steinhöfel et al. 2009), suggesting that the silica in BIF may be derived from mixed hydrothermal and continental sources.

Prerequisites for BIF deposition necessitate not only a source of Si and soluble (reduced) Fe but also a way to oxidize Fe^{2+} into insoluble Fe^{3+} (Fig. 3).

Traditional models of BIF deposition propose that Fe^{2+} was oxidized in the presence of free oxygen derived from oxygenic microbial photosynthesis by cyanobacteria (Cloud 1965) and later through the direct utilization of O_2 by aerobic chemolithoautotrophic bacteria (Holm 1989):

Indeed, the most voluminous BIFs (e.g., Hamersley Group, Western Australia; Transvaal Supergroup, South Africa) overlap in age with the rise of atmospheric oxygen at ~2.4 Ga. While this suggests that the Fe^{3+} component in these BIF formed via an oxic mechanism, the low atmospheric oxygen concentrations in the Archean suggest that the pre-2400 Ma BIF formed via an anoxic mechanism. Both abiotic and biogenic BIF

formation mechanisms have been suggested. In the latter case, the oxidation of Fe^{2+} into Fe^{3+} in an anoxic world can occur via anoxygenic phototrophy, whereby some photosynthetic bacteria (e.g., green and purple sulfur bacteria) can use Fe^{2+} as an electron donor for carbon assimilation instead of water, thus producing Fe^{3+} instead of O_2 (Garrels et al. 1973):

The biogenic precipitation of iron oxides by several species of modern phototrophic bacteria has been observed in both freshwater and marine environments, and laboratory experiments demonstrate that this form of metabolism could generate sufficient quantities of Fe^{3+} to account for all the oxidized iron in BIF (Kappler et al. 2005).

It has also been postulated that the absorption of ultraviolet radiation by either Fe^{2+} or $\text{Fe}(\text{OH})^+$ in the water column could have triggered the hydrolyzation of these species according to the following equation (Cairns-Smith 1978):

Although laboratory experiments have demonstrated that this oxidative process could have generated enough Fe^{3+} to account for all the ferric oxides in BIF, the process remains contentious as the experiments were not done in solutions that actually mimicked Precambrian seawater composition (Konhauser et al. 2007).

The signature feature of many iron formations is the distinctive banding made by alternating assemblages of silica/silicate and iron oxide minerals. Two fundamentally different models have been proposed as to their formation. The first suggests episodic pulsing of an iron-rich plume into the shallow waters of a depositional basin. During periods of upwelling, increased bacterial activity in the photic zone would induce the oxidation of Fe^{2+} to Fe^{3+} , while periods of no upwelling corresponded to low iron mineralization and high silicification from background waters (Morris 1993). Posth et al. (2008) demonstrated

1) Oxygenic Photosynthesis

2) Photoferrotrophy

3) Photooxidation

Banded Iron Formation, Fig. 3 Three simplified models for the oxidation of Fe^{2+} and the deposition of banded iron formations: (1) oxygenic photosynthesis and oxidation of Fe^{2+} by cyanobacterially produced oxygen in

the photic zone; (2) $\text{Fe}(\text{II})$ oxidation in an anoxic water column by photoautotrophs such as green and purple sulfur bacteria; and (3) abiotic oxidation of Fe^{2+} via photooxidation

experimentally that banding could also be due to natural fluctuations in seawater temperature. In the summer, the warm waters promote increased bacterial Fe^{2+} oxidation while maintaining Si in solution, while during the winter, the decline in water temperature diminishes bacterial activity but induces silicification. The second view proposes that banding is the result of postdepositional diagenetic processes in which Si was remobilized and segregated into bands (Trendall and Blockley 1970). Significantly, coupling the reduction of Fe^{3+} minerals to the oxidation of organic matter not only explains the reduced Fe mineralogy in BIF and the low organic-matter content but also explains the abundance of light C isotope signatures associated with the interlayered carbonate minerals (Konhauser et al. 2005).

BIF and Iron Ore

Apart from being an important proxy for Precambrian seawater composition, BIFs are the main source of metallic iron for the steel industry. Almost all iron extracted from BIF-hosted iron ore deposits are used to make pig iron (a mixture of iron ore and coke produced in a blast furnace), which is the main component in the manufacture of steel.

BIF-hosted iron ore deposits can be divided into three classes on the basis of their iron content: (1) iron-rich primary BIFs containing 30–45 wt.% Fe, (2) high-grade martite-goethite ores with 56–63 wt.% Fe, and (3) high-grade hematite ores containing 60–68 wt.% Fe (Clout and Simonson 2005). The bulk of iron ore mined today corresponds to high-grade iron deposits (class 1 and 2) formed by supergene iron enrichment of precursor

BIFs. The supergene enrichment process (Fig. 4) involves deep weathering from the downward movement of oxidizing meteoric fluids that leach out the chert and carbonate components, leaving a residual accumulation of oxidized and hydrous Fe^{3+} phases such as hematite, martite, and goethite (Webb et al. 2003; Clout and Simonson 2005). Martite is often used as a textural term for hematite pseudomorphs after magnetite. The formation of these high-grade iron ores took place long after deposition, likely during the Phanerozoic, when the concentration of atmospheric oxygen, and thus meteoric waters, was sufficient to oxidize precursor mineral phases such as magnetite (Fig. 4).

In some deposits, however, hydrothermal fluids facilitated the formation of high-grade iron ore prior to supergene enrichment. Within the depositional basin, chert bands were hydrothermally replaced by carbonates, which in turn were dissolved and leached during later supergene enrichment (e.g., Taylor and Dalstra 2001).

The world's leading iron ore producers and their historical and future estimated output of Fe are shown in Table 1.

The iron reserves (part of the mineralization that is economically feasible to extract at the time of determination) for each country as in 2011 are also presented. As observed in Table 1, the world output of iron is projected to increase from 2010

to 2013 by about 13%, that is, from 1.32 billion metric tons (Gt) in 2010 to 1.52 Gt in 2013 (Menzie et al. 2013). The world iron resources (parts of the mineralization that is in such form and amount that economic extraction is not feasible) reached ca. 800 Gt of crude ore (defined as it leaves the mine in an unconcentrated form) containing 230 Gt of iron (US Geological Survey, Mineral Commodity Summaries, January 2013).

Superior-type BIF are the largest source of iron used in industry, where three of the largest deposits in the world are located in the Carajás and Quadrilátero Ferrífero iron provinces in Brazil and the Hamersley iron province in Western Australia. These provinces account for close to 40% of the world's iron reserves (Table 1). An example of the magnitude of these BIF deposits is seen within the Hamersley iron province where the Paleoproterozoic Brockman Iron Formation contains some of the largest single lithostratigraphic BIF units known. These units are up to 360 m thick (e.g., the Joffre Member; Haugaard et al. 2016b), having an areal extent of 10^5 km^2 and estimated initial Fe content of $4.3 \times 10^{13} \text{ t}$ at the time of deposition (e.g., Trendall and Blockley 1970).

Table 1 shows that China is the largest producer and importer of iron in the world. The main iron ore reserves of China, however, possess relatively low-grade Fe content (~30% Fe);

Banded Iron Formation, Fig. 4 Sketch showing typical supergene enrichment of a magnetite-rich BIF leading to a high-grade hematite-goethite ore deposit within the weathering zone (Modified from Clout and Simonson (2005))

Banded Iron Formation, Table 1 The world's largest producers of iron 2000–2017 (estimated). See text for details. Values extracted from Menzie et al. (2013) and US Geological Survey Mineral Commodity Summaries, January 2013

Country	Average ore grade (% Fe)	Fe content in thousand metric tons										Reserves in billion tons (Gt)		
		2000	2005	2010	2013	2015	2017	Crude ore (2011)	Fe content			Crude ore (2011)	Fe content	
Australia	62	107,000	163,000	271,000	330,000	350,000	370,000	35,000				35,000	17,000	
Brazil	66	141,000	186,891	247,772	250,000	250,000	260,000	29,000				29,000	16,000	
Canada	64	22,700	19,333	23,300	28,000	28,000	30,000	6300				6300	2300	
China	64	73,600	134,000	350,000	410,000	420,000	430,000	23,000				23,000	7200	
India	64	48,600	97,500	166,000	170,000	172,000	174,000	7000				7000	4500	
Russia	58	50,000	56,100	58,500	59,000	59,500	60,000	25,000				25,000	14,000	
South Africa	62–65	21,570	24,900	36,900	46,700	48,900	49,500	1000				1000	650	
Ukraine	55	30,600	37,700	43,000	45,000	48,000	50,000	6000				6000	2100	
USA	–	39,703	34,202	32,000	32,000	32,000	32,000	6900				6900	2100	
World		607,000	837,00	1,320,000	1,520,000	1,660,000	1,750,000	170,000				170,000	80,000	

therefore, high export rates of high-grade iron ore are expected from China's largest suppliers in the future (e.g., Australia and Brazil).

Future Directions

As marine chemical precipitates, BIFs hold great importance as proxies for ancient seawater chemistry and, in this regard, may provide new insights into the composition of the ancient marine biosphere and, ultimately, the atmosphere, through the biogenic gases that ancient plankton emitted. Recent studies have begun to examine changing Precambrian seawater chemistry in terms of bioessential trace metals, and the results obtained from the BIF record are being corroborated by the record of these trace metals in marine black shales (e.g., Zn; Scott et al. 2012). Future work on BIF will undoubtedly investigate the temporal variations in more metals. Such geochemical studies will be enhanced by new analytical developments in trace metal stable isotopes, whereby relatively novel metal isotopes (e.g., $\delta^{53}\text{Cr}$ and $\delta^{238}\text{U}$) or multi-isotope surveys (e.g., combining $\delta^{56}\text{Fe}$ and $\delta^{30}\text{Si}$; Steinhöfel et al. 2009) will improve our understanding of the paleoredox conditions under which BIF formed. New BIF-based studies examining the paleoredox conditions a few million years prior to and after the great oxidation event (GOE, ca. 2.45 Ga) indicate that this event likely occurred more gradually than previously thought. As the products of the interplay between the mantle, the ocean, and the biosphere, BIFs are important chemical archives of ancient seawater composition. They not only grant us an understanding into ancient mantle and surface process systematics but also provide important insights into the evolutionary pathways of early life.

Bandpass

Daniel Rouan
Observatoire Paris-Site de Meudon, Meudon,
France

Definition

The bandpass is a well-defined range of frequencies (or wavelengths) determined by a filter

that cuts out all other frequencies (or wavelengths) above and below this band. In visual and infrared photometry, different sets of standard filters with well-defined bandpasses have been defined and are used to perform color photometry. A given set defines a photometric system, the measured values in the different filters being generally given in ► [magnitudes](#).

Sediment · South Africa · Traces of life

Definition

The Barberton greenstone belt in South Africa is one of the best-preserved successions of mid-Archean (3.57–3.21 Ga) supracrustal rocks in the world, together with the ► [Pilbara Craton](#) in Western Australia. As such, it is a remarkable natural laboratory where conditions and processes at the surface of the Archean Earth can be studied in detail. The volcanic sequences include thick flows of ► [komatiite](#), a type of ultramafic lava named after the Komati River that flows through the belt, and records of large phreatomagmatic eruptions. Sedimentary sequences include ► [cherts](#), ► [banded-iron formations](#), and barite whose compositions constrain the composition and temperature of Archean oceans and preserve some of the earliest traces of life on Earth. The granitic rocks and metamorphic sequences provide information about Archean tectonic processes.

History

Geological mapping and research has been carried out in the Barberton belt over much of the past century, but only in the 1970s did its geological significance become apparent. Three developments were particularly important: The first was the development of increasingly accurate age dating that revealed the emplacement of volcanic and sedimentary rocks between 3.5 and 3.2 Ga ago (e.g., Lopez Martinez et al. 1984; Armstrong et al. 1990). This discovery showed that the Barberton terrain, together with those of the Pilbara Craton in Western Australia, contained the oldest known, well-preserved (i.e., metamorphosed to only a low degree) volcanic and sedimentary sequences. The second important discovery was the recognition by Richard and Morris Viljoen of the University of the Witwatersrand that many of the ultramafic rocks of the sequence were volcanic. They named this new rock type komatiite after the Komati River that flows through the belt. The geological and tectonic significance of these rocks has been developed in numerous publications (e.g., Viljoen and Viljoen 1969; Anhaeusser 1980; Jahn et al. 1982; de Wit et al. 1987; Dann 2000). The third important development stemmed from the work on clastic and chemical sedimentary rocks. Following the recognition of the ancient age of the sedimentary sequences in the 1970s, several research groups undertook a systematic search for microfossils in carbonaceous black ► [cherts](#) and shales. Detailed sedimentological and geochemical studies followed and led to major advances in the understanding of surface processes on the early Earth, including the observation of shallow-water sedimentary rocks and silicified evaporites (Lowe and Knauth 1977), sedimentary barite horizons (Heinrichs and Reimer 1977), seafloor alteration (Duchac and Hanor 1987), seafloor hot springs (de Ronde and Ebbesen 1996), semiquantitative evidence for tides (Eriksson and Simpson 2000), a record of temperature of the Archean ocean (Knauth and Lowe 2003), and photosynthetic microbial mats (Tice and Lowe 2006). In addition, it was found that at least four sedimentary beds in the

Barberton belt contained sand-sized spherical particles (spherules) interpreted to have formed by condensation of clouds of impact-generated rock vapor and thus represent the oldest terrestrial impact deposits (Lowe et al. 2003; Hofmann et al. 2006; Ozdemir et al. 2017).

Overview

The Barberton greenstone belt is a small, cusp-shaped succession of volcanic and sedimentary rocks invaded on all sides by granitoid plutons or truncated by ductile shear zones. It is located in the Mpumalanga province of South Africa, about 350 km east of Johannesburg. It is world famous for its komatiites, a type of ultramafic lava named after the Komati River that runs through the southern part of the belt, and for thick sequences of sedimentary rocks, which have yielded some of the earliest records of early life and of Earth's early surface conditions. The greenstone sequences, assigned to the ► [Barberton Supergroup](#), have been subdivided into three stratigraphic units. From base to top, these are (1) the Onverwacht Group, dominated by ultramafic and mafic volcanic rocks; (2) the Fig Tree Group, a volcano-sedimentary succession made up of graywackes (a variety of sandstone with a clay-rich matrix), shales, cherts, and felsic volcanoclastic rocks; and (3) the Moodies Group, characterized by coarse-grained clastic sedimentary rocks, mainly sandstones and conglomerates. Geological mapping has provided an increasingly clearer picture of the detailed stratigraphy despite the complex structure (Lowe et al. 2012). The protracted, 350-million-year-long evolution of the region encompassed multiple tectonic events that include three or more cycles of volcanism and sedimentation, deformation, and granite intrusion (Lowe 1999). This rich history led de Wit et al. (1992) to use the region as the basis of their model for the formation of continental crust.

Extensive field-based studies in the Barberton belt, starting from the early 1960s, provided evidence for the existence, as early as 3.5 Ga, of

a rich microbial ecosystem. Spherical, coccoidal, rod-shaped, and filamentous microscopic structures made up of carbonaceous matter and interpreted as microfossils have been recorded from Onverwacht and Fig Tree Group cherts. These rocks were deposited in shallow and deep marine environments, possibly in part on normal Archean oceanic crust and possibly associated with hydrothermal activity (Walsh 1992; Altermann 2001; Westall et al. 2001, 2015; Tice and Lowe 2006; Hickman-Lewis et al. 2018; Gourier et al. 2019; Homann 2019).

Domal stromatolites are also present in the Barberton belt (Byerly et al. 1986), but their origin, together with other early Archean occurrences, is controversial (Lowe 1994). More recently, Furnes et al. (2004) reported micrometer-scale tubular structures, interpreted to represent bioerosion features, in the rims of Onverwacht Group pillow basalts. Stable isotopic data have revealed the possible emergence of diverse groups of prokaryotes including carbon-fixing Bacteria and Archaea, methanogens, sulfate reducers, and possibly photosynthesizers. Structures reminiscent of modern microbial mats in shallow-water sandstones are widespread in parts of the Moodies Group (Heubeck 2009; Gamper et al. 2012).

The sedimentary sequences themselves can be mapped in detail and measured at high stratigraphic resolution. They thus provide abundant information about conditions at the Earth's surface: the spatial and temporal sequence of depositional systems; the interface between various regimes of erosion, transport, and deposition; the diagenetic processes near the surface; structural control on sedimentary composition, thickness, and geometry; the thermal history and evolution of sedimentary basins; and thus the overall geodynamic setting on the early Earth.

The ultramafic lavas of the Barberton belt have unusual compositions that define the Al-depleted or Barberton-type komatiite (Nesbitt and Sun 1976; Arndt et al. 2008). These rocks are formed through melting under unusual conditions in the mantle. Controversy surrounds the exact setting: most geologists support a model in which the

melts form in an unusually hot mantle plume (e.g., Arndt et al. 2008), but others advocate melting in cooler conditions in an Archean subduction zone (e.g., Grove and Parman 2004). Resolution of the issue has important implications for our understanding of Archean geodynamics. Despite more than 30 years of research, very few complete chemical analyses of Barberton komatiites are available, yet this information is crucial if the potential of these rocks as tracers of Archean geodynamic processes is to be realized. Black and white smokers on the Archean ocean floor, the exits of hydrothermal fluids that circulated through basaltic crust, could represent one possible setting for the emergence and evolution of life (Russell et al. 2005). Examples of these may well exist in the Barberton greenstone belt, but, as for most of the crucial geological and biological aspects of the Archean mentioned above, also these are the subject of considerable debate (e.g., de Ronde and Ebbesen 1996; Lowe and Byerly 2007).

Future Directions

Much of future work in the belt will focus around scientific drilling projects that are aimed at recovering continuous sections of well-preserved volcanic and sedimentary rocks. Work on the sedimentary sequences will provide information about erosion and sedimentation on the early Earth, the composition and temperature of Archean seawater, and possible sites where life may have emerged and evolved. The study of tidal sequences will provide information about the dynamics of the Earth-Moon system, and the investigation of spherule layers (including impact debris) provides information about the nature and magnitude of meteorite impacts on the early Earth. Work on the ultramafic to felsic volcanic rocks will provide new insights into volcanic processes, dynamics of the crust and mantle, and the interaction between oceanic volcanic crust and the hydrosphere and biosphere. The sources of hydrothermal fluids on the ocean floor, driven by the circulation of seawater through the volcanic pile,

constitute a second habitat of early life. Work on deeper sections through the lower parts of the succession will provide information about tectonic processes that operated during deposition of volcanic, sedimentary, and granitic rocks and during accretion of these materials to the continent.

Archean Eon · Chert · Sedimentary rock · Onverwacht Group · Fig Tree Group · Moodies Group

Definition

► **Sedimentary rocks** can be found throughout the ► **Barberton Supergroup**. In the volcano-sedimentary Onverwacht Group, sedimentary rocks make up less than 5% of the succession. They consist of bedded ► **cherts**, representing a variety of silicified clastic, chemical, and biogenic sediments. Deep- to shallow-marine, fine-grained siliciclastic sedimentary rocks make up the dominant part of the Fig Tree Group. The Moodies Group is characterized by relatively coarse-grained, siliciclastic, alluvial, fluvial, shoreline, and shallow-marine deposits. Detailed sedimentological and geochemical studies of the sedimentary rocks of the Barberton Supergroup have provided major advances in the understanding of surface processes in the Paleoarchean.

Overview

Bedded chert horizons of the Onverwacht Group are typically 1–20 m thick and represent interflow sedimentary units that were deposited on the seafloor between phases of extrusive submarine volcanic activity. The cherts consist of a variety of

Barberton Greenstone Belt, Sedimentology,

Fig. 1 Carbonaceous chert with discontinuous layers of silicified ultramafic ash (*gray chert*) showing ripple lamination (characteristic of subaqueous deposition). Onverwacht Group, Kromberg Formation, Farm Josefsdal

silicified sediments (Lowe 1999; Tice and Lowe 2006; Hofmann et al. 2013). Extensive early silicification took place as a result of low-temperature hydrothermal activity on the seafloor, resulting in excellent preservation of the sedimentary strata. Silicified volcanoclastic sediments are common and include silicified beds of ultramafic to mafic ash and accretionary lapilli. Laminated cherts of various shades of gray to black represent mixtures of volcanoclastic material and carbonaceous matter (Fig. 1). Deposition took place in low-energy, predominantly sub-wave base settings with episodic, high-energy current events during which coarse-grained volcanoclastic material and, in rare cases, meteorite impact ► *ejecta* were deposited. Cherts have been used extensively to study surface processes, seawater composition, and life in the Archean.

The Fig Tree Group consists of a 2–3 km thick, largely siliciclastic, and volcanoclastic sequence that is capped by felsic volcanic and volcanoclastic rocks (Heinrichs 1980; Lowe and Nocita 1999; Hofmann 2005; Drabon et al. 2019). In the southern part of the belt, a variety of siliciclastic lithofacies with abundant felsic volcanic detritus are present that formed in deep- to shallow-water, fan delta, and alluvial environments (southern facies). The local presence of beds of jaspilitic banded iron formation, chert, and barite indicates syndepositional hydrothermal activity. In the northern part of the Barberton greenstone belt, the Fig Tree Group is mainly characterized by turbiditic

sandstones and shales that formed in relatively deep-water environment (northern facies). Several spherule beds of quenched liquid silicate droplets in the Fig Tree Group represent fallout and partially tsunami-reworked meteorite impact deposits (Lowe et al. 2014).

The ► *Moodies Group* consists of up to 3.7 km thick, quartz-rich, predominantly arenaceous rocks, in contrast to the quartz-poor and matrix-rich Fig Tree graywackes. It consists of alluvial conglomerate, braided fluvial, tidal and shallow-marine sandstones, and minor siltstone and banded iron formation (Anhaeusser 1976; Heubeck and Lowe 1994; Heubeck 2019). Intertidal sedimentary rocks and microbial mat-related sedimentary structures are locally well preserved (Homann et al. 2015). Moodies strata may include some of the oldest preserved aeolian deposits (Simpson et al. 2012). Deposition of the Moodies Group was syntectonic with final greenstone belt deformation and occurred within only a few Ma under initially extensional and later compressional deformation (Heubeck 2019).

Definition

The Barberton Greenstone Belt is an ensemble of lightly to moderately metamorphosed igneous rocks and sediments dating between about 3.5 and 3.2 billion years old (Ga). Together with the similarly-aged Pilbara Greenstone Belt, it is one of the only two locations in the world hosting the oldest, well-preserved sediments.

Overview

The Barberton greenstone belt of South Africa and Swaziland, together with the greenstone belts of the Pilbara region in Australia, hosts the oldest (3.5–3.3 Ga) well-preserved rocks containing fossil signatures of life. These traces occur in thin layers of volcanoclastic sediments, sandwiched between thick successions of mostly mafic to ultramafic volcanic lavas. The remains of

Barberton Greenstone Belt, Traces of Early Life, Fig. 1 Barberton Greenstone Belt, traces of early life. (a) Purported microbial tunnels in the vitreous rind of an ~3.4 Ga-old pillow lava from the Barberton Greenstone

microbial mats are relatively common in shallow-water deposits dating to almost 3.5 Ga, while deeper-water deposits contain reworked, detrital remains of organic matter and microbial mats. More recently identified remains of chemotrophic colonies co-located with hydrothermal influence complement the microbial diversity. Somewhat younger clastic sediments of the 3.2 Ga Moodies Group have yielded relatively large cellular remains of possible planktonic organisms and abundant microbial mats.

The Palaeo- to Mid-Archaeon (3.5–3.2 Ga) Barberton greenstone belt consists of kilometer-thick, largely subaqueous volcanic rocks and their erosional products, together with sedimentary rocks including BIFs, cherts, shales, baryte, siltstones, sandstones, and conglomerates. Largely mafic to ultramafic lavas were extruded onto relatively shallow-water platforms. Interspersed with these volcanics are thin horizons of volcanoclastic and hydrothermal sediments deposited at water depths ranging from littoral to sub-wave base. Early diagenetic silicification of sediments and underlying volcanics was related to circulating hydrothermal fluids (Hofmann and Bohlar 2007; Westall et al. 2015; Hickman-Lewis et al. 2020a) and seawater oversaturation with respect to silica (Lowe and Byerly 1986). These sediments host a variety of traces of early life.

Early studies reported the occurrence of possible cellular microfossils (e.g. Walsh 1992). Microbial corrosion features, typical of those produced by chemolithotrophic microorganisms in the vitreous rinds of pillow lavas, were described by Furnes et al. (2004, Fig. 1a) from the Hoogenoeg Formation (ca. 3.4 Ga) but their biogenicity has been questioned (Grosch et al. 2014; Grosch and McLoughlin 2014). These once hollow structures

in the outer glassy layers of pillow basalts are lined by Ti-oxides that contain early sulphide inclusions showing $\delta^{34}\text{S}$ depletions (–45‰ to –3‰), which is consistent with a biogenic origin for the sulphides. No microfossils are associated with these tunnels.

The surfaces of volcanoclastic sediments deposited in shallow-water environments such as the Buck Ridge and Josefsdal Cherts hosted microbial mats and biofilms which were probably formed by anaerobic photosynthetic organisms. When observed in petrographic thin sections, they are characterized by packets of fine-grained, carbon-rich layers that form more or less continuous wispy, wavy horizons on sediment surfaces (Fig. 1b, c) (Walsh 1992; Tice and Lowe 2004; Tice 2009; Westall et al. 2006, 2015) and occur even in the oldest preserved sediments in Africa, the 3.472 Ga Middle Marker Formation (Hickman-Lewis et al. 2018). Biogeochemical signatures from these mats are consistent with diverse bacterial and archaeal precursors (Hickman-Lewis et al. 2020a). Tice (2009) demonstrated that environmental factors, such as current energy, controlled the style of microbial mats preserved in the 3.42 Ga-old Buck Reef Chert. Formed at water depths between storm base and fair-weather wave base, anastomosing and mesh-like mats occur in sediments consisting of coarse-grained fluffy carbonaceous grains, while finely laminated mats occur in finer-grained sediments deposited under quiet conditions. Importantly, Hickman-Lewis et al. (2020b) documented the influence also of riverine water on the development of phototrophic mats.

Rarely, carbonaceous filaments and spheroids considered potential microfossils are observed in silicified interstitial spaces between mat layers (Walsh 1992, Fig. 1d). Although the organisms

Barberton Greenstone Belt, Traces of Early Life, Fig. 1 (continued) Belt now questioned (Furnes et al. 2004; Grosch and McLoughlin 2014). (b) Tufted phototrophic biofilms from the 3.472 Ga Middle Marker Formation (Hickman-Lewis et al. 2018). (c) Well-preserved silicified filaments in a microbial biofilm from the 3.33 Ga Josefsdal Chert, Barberton (Westall et al. 2006b). (d) Thin-section photomicrograph of a potentially photosynthetic filamentous microbial mat from ~3.4 Ga-old cherts from Barberton (Walsh 2004). (e) 3-D stellate

chemotrophic colonies and (f) Raman spectral mapping of chemotrophic clots from the 3.33 Ga Josefsdal Chert, Barberton (Westall et al. 2015; Hickman-Lewis et al. 2020b). (g) Filamentous moulds from the vadose zone in the 3.2 Ga Moodies Group sandstones, Barberton (Homann et al. 2016). (h) Acritarch (organic-walled vesicle of unknown biological affinity) from 3.2 Ga siliciclastic sediments of the Moodies Group, Barberton (Javaux et al. 2010)

forming the mats are seldom preserved, a scanning electron microscope study of an extremely well-preserved silicified biofilm in the 3.33 Ga Josefsdal Chert documented the presence of filaments 0.25 μm in diameter and tens of microns in length embedded in chert interpreted as a thick polymer on the mat surface (Westall et al. 2006b, Fig. 1c). Detailed in situ morphological and geochemical analysis of this particular biofilm demonstrated that the biofilm had been undergoing incipient calcification, probably due to the action of sulphate-reducing microorganisms degrading the lower, dead layers of the biofilm prior to early silicification that preserved it in three dimensions (Westall et al. 2011b).

Silicified sediments also contain particles and clots of carbon that may be derived from microbial colonies. Carbon and sulfur isotope signatures have been interpreted to indicate the presence of a variety of microbial organisms, including anoxygenic photosynthesisers, and heterotrophs such as methanogens (see reviews in Westall 2011; Homann 2019; Hickman-Lewis et al. 2020c). Thick (>30 μm), spicular carbonaceous coatings on volcanic particles and stellate, 3D carbonaceous clots (Fig. 1e, f) formed in a mixture of silica gel and very fine volcanic ash document the presence of colonies of chemotrophic microorganisms in these cherts (Westall et al. 2015; Hickman-Lewis et al. 2020c). Carbon isotope signatures (averaging -21.0% to -11.5% , as well as the selective accumulation of transition metals (Fe, V, Ni, As, and Co) of biological (metallomic) importance within these clots, reinforce their biogenicity, possibly suggesting methane and/or nitrogen cycling chemotrophic metabolisms (Hickman-Lewis et al. 2020c).

Younger littoral sediments from the 3.2 Ga Moodies Group have revealed a wealth of fossil microbial structures. Crinkled, domed, and anastomosing photosynthetic microbial mats occur on the surfaces of coarse-grained, tidal-zone, and riverine sandstones (Noffke et al. 2006; Heubeck 2009; Homann et al. 2015). Vadose zone cracks in the sandstones reveal the moulds of microorganisms that have been compared with modern endoliths (Homann et al. 2015). Coeval siltstones have yielded

compressed remains of large (up to 300 μm diameter) organic, hollow, and spherical structures (acritarchs) interpreted as unicellular microorganisms or colonial envelopes (Javaux et al. 2010), thus documenting the existence of a diverse biota.

Barberton Supergroup

Axel Hofmann

Department of Geology, University of Johannesburg, Johannesburg, South Africa

Synonyms

Swaziland Supergroup (outdated)

Definition

The volcano-sedimentary sequence that forms the Barberton greenstone belt has been grouped stratigraphically as the Barberton Supergroup, renamed from the Swaziland Supergroup of older literature. The Barberton Supergroup formed ~3.55–3.22 Ga ago and is subdivided, in ascending order, into three major stratigraphic units: (1) The Onverwacht Group (3.55–3.25 Ga) dominantly consists of submarine ultramafic-mafic volcanic rocks and minor felsic volcanic and silicified ► [sedimentary rocks](#). (2) The Fig Tree Group (3.26–3.23 Ga) is comprised of shale, greywacke, and felsic volcanoclastic rocks with minor conglomerate, chert, barite, and banded iron formation. (3) The Moodies Group (~3.22 Ga) consists of shallow marine to fluvial sandstone and conglomerate with minor mafic volcanics, shale, and banded iron formation. These groups have been subdivided into a number of formations, which differ in lithology, thickness, and facies across the major fault zones that separate the Barberton greenstone belt into discrete fault-bounded segments. The

excellent degree of preservation and exposure, continuous outcrop of mostly subvertically dipping strata, and the high lithologic variability made possible the detailed mapping of the units of the Barberton Supergroup. This in turn provided the base for targeted research that led to major contributions to the understanding of the Archean.

Barite

Christoph Heubeck
Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Jena, Germany

Definition

Barite (also Baryte), BaSO_4 , is a widespread, usually white or colorless mineral which can be deposited by biogenic, hydrothermal, and evaporitic processes. In sedimentary environments, the main sources of barium ions are submarine hydrothermal vents; the sulphate ion is common in Phanerozoic seawater.

The origin of primary stratiform bladed baryte crystals on Archean sea floors (“crystal lawns”) is debated because the highly oxidized sulfate ion is generally thought to have been in short supply in Archean oceans. However, some of these barite deposits may have formed from sulfate which had been generated photolytically as aerosols in the Archean atmosphere and then washed into the oceans. Others may be late-diagenetic

pseudomorphs after calcium sulphate. Studies on S isotopes indicate that some barite played a role in bacterial sulphate reduction, one of the earliest metabolic processes.

Barycenter

David W. Latham
Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA

Synonyms

[Center of mass](#)

Definition

In astronomy, the barycenter is the center of mass of a system of two or more bodies. For the purposes of most calculations, the system can be considered to be concentrated at the position of the barycenter, with a total mass equal to the sum of the masses of the individual objects. The barycentric radial velocity of an object, such as a star, as measured by a terrestrial observer is calculated relative to the center of mass of the Solar System. This is slightly different from the heliocentric velocity of such a star, which is centered on the Sun and varies slightly with time according to the position of the planets (since the motion of the planets produces slight changes in the Solar System’s barycenter).

Basalt

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Basalt is a fine-grained, dark-colored ► [mafic igneous rock](#) erupted at the surface of the Earth and other rocky planets (volcanic rock). Basalt contains 45–52% of SiO₂ and is composed of plagioclase (50%), ortho- or clinopyroxene (25–40%), and minor Fe-Ti oxides (2–3%), with or without ► [olivine](#) (10–25%). Porphyritic samples contain large crystals (phenocrysts) of olivine, pyroxene, or plagioclase dispersed in a fine-grained glassy matrix, also called ground-mass. Gas-rich samples contain abundant vesicles. Basalt erupts as ► [pillow lava](#), thick sheet flows, or fragmental scoria. It is the most common rock of the Earth's ► [oceanic crust](#) – which is produced at the ► [mid-ocean ridges](#) – and in lunar *maria* (ancient flood-basalt plains corresponding to the dark surfaces of the Moon). Basalt is also present in the crust of Mars and Venus. It forms by partial melting of the mantle and erupts in diverse tectonic settings: midocean ridges, oceanic islands, subduction zones, continental rifts, and volcanic plateaus.

Bathybius Haeckelii

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Definition

In June 1857, the Britannic ship “The Cyclops” found a very special matter on the bottom of the North Atlantic Ocean. Some chemists and biologists considered that it was a very simple living matter and thought that it resolved the problem of the origin of life. Indeed, according to them, it constituted an example of spontaneous generation and a link between inert matter and living matter. Thomas Huxley (1825–1895) himself named it *Bathybius haeckelii*. However, in 1876, a chemist revealed that it was calcium sulfate and not living matter.

Discussions about *Bathybius* took place during the period of the debate about spontaneous generations. Therefore, during few years the possibility of the production of this matter, very closed to living matter, was highly considered by many chemists and biologists.

Beagle 2

Frances Westall

Centre de Biophysique Moléculaire, CNRS, Orléans, Cedex 2, France

Definition

The Beagle 2 lander, named after the famed ship in which Charles Darwin traveled the world, was part of the ► [European Space Agency's](#) Mars Express mission. It was launched in June 2003 and was supposed to land in December 2003. Unfortunately, all contact with the 33.2 kg lander was lost a few days before touchdown, and its fate remains a mystery. The lander was a compact assemblage of instruments designed to address science questions ranging from the search for traces of past and extant life, measurement of the composition of the atmosphere and other environmental parameters, the oxidation state at the surface, and analysis of the geomorphology of the landing site in a sedimentary Basin of Isidis Planitia.

Overview

The lander was constructed by a British consortium, coordinated by Prof. Colin Pillinger of the Open University. It was equipped with a 75 cm long robotic arm holding at its end an array of instruments called the PAW (Payload Adjustable Workbench) that included stereo cameras, a Mössbauer spectrometer to measure the oxidation states of iron-containing compounds, an X-ray spectrometer for determining mineral composition, and a (dentist's) drill for collecting samples. Also onboard the lander was a gas analysis package (GAP) that included a gas chromatograph-

mass spectrometer to analyze carbon isotopes as a signature for life. Finally, a “mole” or subsurface sampler (PLUTO – Planetary Undersurface Tool) was designed to penetrate beneath the loose regolith surface to obtain samples for analysis.

The 1 m diameter lander was equipped with a UHF radio antenna, telecommunications, a battery, electronic processors, heaters, solar panels, and other payload instruments, such as radiation and oxidation sensors to address the environmental objectives of the mission. Upon arrival, the lander was supposed to have broadcast a piece of music specially composed by the British rock band Blur.

Various hypotheses involving malfunctioning of various pieces of equipment have been put forward to explain the failure of the mission. The lander could have bounced off the atmosphere of Mars and burned up, or the parachute failed to deploy and/or the airbags did not function and the lander crashed onto the Martian surface, or perhaps the backshell became entangled with the parachute, the parachute could have covered the lander, thus preventing it from opening. At the beginning of 2015 it was announced that the orbital camera around Mars, HiRISE, had found the lander intact on the Martian surface, within the expected landing ellipse in Isidis Planitia but, unfortunately, it appeared to be only partially deployed. However, it can be demonstrated that the entry, descent and landing system did indeed work.

(101955) Benu

- [RQ36](#)

Benu Asteroid

Anny-Chantal Levasseur-Regourd
Sorbonne Univ., Campus P. & M. Curie /
LATMOS, Paris, France

Synonyms

[Asteroid 101955](#)

Definition

(101955) Benu is a near-Earth carbonaceous asteroid, suggested to belong to the taxonomic class B or more likely to the rare class F (Belskaya et al. 2005) from its spectropolarimetric properties (Cellino et al. 2018). It has been the target of the NASA OSIRIS-REx sample return mission, which rendezvoused with it in late 2018 and collected samples in 2020. The return capsule should reach Earth in September 2023 and allow detailed analyses of the samples, as well as comparisons with those returned from asteroid Ryugu.

Benu is (like asteroids Steins and Ryugu) a roundish, diamond-shaped body with an equatorial bulge, probably formed by re-accumulation of rubble ejected after catastrophic disruption of a larger parent body. Its mean size is ≈ 490 m, and

its rotation period ≈ 4.3 h. Its low density ($\approx 1190 \text{ kg m}^{-3}$) suggests a huge bulk porosity, as expected for a “rubble-pile” asteroid (Barnouin et al. 2019). Its surface gravity is thus extremely low, about only 6.27 micro-g at its equator. The surface of Benu is rough, with boulders including minerals likely to originate from its parent body, and quite dark, with a geometric albedo of $\approx 4.4\%$ (Hergenrother et al. 2020), comparable to that of cometary nuclei (Lamy et al. 2004).

Benu is a most remarkable active asteroid, which appears to eject plumes of particles, with sizes up to ≈ 10 cm (Hergenrother et al. 2020). They could possibly be released after meteoroid impacts or dehydration of abundant hydrated minerals, such as phyllosilicates (Hamilton et al. 2019). Information retrieved from remote observations of the linear polarization of solar light scattered by the surface and near-environment of Benu (Cellino et al. 2018) fairly agrees with that of comet Hale-Bopp, under similar observational conditions. Analyses of Benu samples should thus provide more insight into active asteroids and main-belt comets, together with clues on the evolution of carbonaceous matter in the Solar System.

Benzene (C₆H₆)

William M. Irvine
Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

C₆H₆; Cyclohexa-1,3,5-triene

Definition

Benzene is an ► [aromatic hydrocarbon](#) in which the six carbon atoms are arranged in a ring, with all carbon bonds equal and intermediate in length between single and double bonds. Under standard laboratory conditions benzene is a colorless and highly flammable liquid with a sweet smell.

Benzene is a known carcinogen and has various toxic effects on humans.

History

Benzene was first isolated by the English chemist/physicist Michael Faraday in 1825, although the natural aromatic resin that contains benzene comes from Southeast Asia and was known to Arab traders during the Middle Ages. The cyclic structure of benzene was announced in 1865 by the German chemist Friedrich A. Kekulé, with the data on carbon bond lengths coming from X-ray diffraction measurements. An astronomical detection in the protoplanetary nebula CRL 618 has been reported by Cernicharo et al. (2001) from mid-infrared observations, and the measured abundance is matched by chemical models (Woods et al. 2003). In the Solar System benzene has been observed in the atmospheres of Jupiter, Saturn and Saturn's moon Titan (Fouchet et al. 2005), and in comet 67P/Churyumov-Gerasimenko (Schuhmann et al. 2019).

Definition

Benzonitrile (C₆H₅CN) is an aromatic hydrocarbon molecule, consisting of a benzene ring functionalized by a cyano (CN) group. It was the first benzene-ring containing a molecule to be detected by radio astronomy and was observed toward the dark cloud TMC-1.

History

The detection of benzonitrile was first reported by McGuire et al. (2018) in Green Bank Telescope observations of the TMC-1 dark cloud at cm-wavelengths. Benzonitrile is an aromatic molecule and the first such molecule to be detected by radio astronomy that contains the benzene subunit. Polycyclic aromatic hydrocarbons (PAHs), large organic molecules consisting of multiple fused aromatic rings, typically benzene, are expected to contain 10–25% of the interstellar carbon reservoir based on observations of the bright emission features known as the

Unidentified Infrared Bands. These PAHs are thought to primarily be produced in evolved stars; however, the detection of benzonitrile, a simple cousin, in a cold, starless dark cloud like TMC-1, offers an alternative formation pathway. Detailed studies of the formation of this molecule suggest that the CN-addition to benzene is barrierless and efficient in interstellar conditions, suggesting that benzonitrile is likely an excellent radio-observable proxy for benzene in the study of PAH formation and evolution (Lee et al. 2019; Cooke et al. 2020). Since the original detection, benzonitrile has been detected toward four additional prestellar sources, indicating aromatic molecules are ubiquitous in the earliest stages of star formation (Burkhardt et al. 2021). In addition, several other simple rings have been detected in TMC-1, including both isomers of cyanocyclopentadiene (c-C₅H₅CN; McCarthy et al. 2021; Lee et al. 2021) and both isomers of cyanonaphthalene (c-C₁₀H₇CN; McGuire et al. 2021). Recent chemical modeling efforts using the nautilus code (Ruaud et al. 2016) and the Kinetic Database for Astrochemistry (KIDA) network (Wakelam et al. 2015), modified to include the formation of aromatic molecules, found that the observed abundances of simple rings are greater than the model's prediction by several orders of magnitude, suggesting that the current understanding of the formation of aromaticity is incomplete.

Definition

BepiColombo is a joint mission between the European Space Agency (ESA) and the Japanese Aerospace Exploration Agency (JAXA) to explore Mercury, the innermost planet of our Solar System. It consists of two orbiters, the Mercury Planetary Orbiter (MPO) and the Mercury Magnetospheric Orbiter (nicknamed Mio). Both spacecraft has been launched with an ARIANE V rocket on 20 October 2018 for an arrival at Mercury in late 2025. From their dedicated orbits, the two spacecraft will be studying the planet and its environment. On its route, BepiColombo (Fig. 1) will pass by Earth, two times Venus, and six times Mercury.

History

More than 30 years ago, Mercury was seen as not very spectacular and it also gave no reasons for speculations about active surface processes, e.g., volcanism. The view of Mercury drastically changed after the very successful MESSENGER mission of NASA (McNutt et al. 2006). MESSENGER revealed some results which did not fit in our current thinking of how Mercury should have evolved or what one expected to find on a planet close to the Sun. Volcanism has played a critical role in shaping Mercury's surface, Mercury is abundant in volatile elements, Mercury showed a geologic landform called Hollows not yet been seen on other planets, and Mercury has an Earth like magnetic field albeit much weaker. In addition, Mercury is a key planet to understand

BepiColombo, Fig. 1 BepiColombo cruise configuration

the evolution history of our Solar System because of its position among the planets. It is the planet closest to the Sun and experiences the harsh environment of the Sun the most.

A suite of state-of-the-art scientific instruments, flying on the two BepiColombo spacecraft, allow to address these wide range of scientific questions. The science payload of MPO contains 11 instruments: **BELA** (BepiColombo Laser Altimeter) to characterize the topography and surface morphology of Mercury (Thomas et al. 2021), **ISA** (Italian Spring Accelerometer) to study Mercury's interior structure and to test Einstein's Theory of Relativity (Santoli et al. 2020), **MPO-MAG** (Magnetic Field Investigation) an instrument to describe Mercury's magnetic field and its source (Heyner et al. 2021), **MERTIS** (Mercury Radiometer and Thermal Imaging Spectrometer) to study Mercury's mineralogical composition and provide global temperature maps (Hiesinger et al. 2020), **MGNS** (Mercury Gamma-Ray and Neutron Spectrometer) to determine the elemental compositions over the entire surface of Mercury (Mitrofanov et al. 2021), **MIXS** (Mercury Imaging X-ray Spectrometer) an instrument that uses X-ray fluorescence analysis to provide a global map of the surface atomic composition (Bunce et al. 2020), **MORE** (Mercury Orbiter Radio science Experiment) two-way, multifrequency radio science measurements to describe Mercury's gravity field (Iess et al. 2021), **PHEBUS** (Probing of Hermean Exosphere by Ultraviolet Spectroscopy) an UV spectrometer to characterize the composition and dynamics of Mercury's exosphere (Quémerais et al. 2020), **SERENA** (Search for Exosphere Refilling and Emitted Neutral Abundances) a suite of four sensor units to study the interactions between the surface, exosphere, magnetosphere, and the solar wind (Orsini et al. 2021), **SIMBIO-SYS** (Spectrometers and Imagers for MPO BepiColombo Integrated Observatory) a camera and spectrometer system to provide global, high-resolution, and IR imaging of the surface (Cremonese et al. 2020), and **SIXS** (Solar Intensity X-ray and particle Spectrometer) to perform measurements of solar X-rays and particles (Huovelin et al. 2020). The science payload of

Mio contains five instruments or instrument suites: **MGF** (Magnetic Field Investigations) an instrument to provide a detailed description of Mercury's magnetosphere and of its interaction with the planetary magnetic field and the solar wind (Baumjohann et al. 2020), **MPPE** (Mercury Plasma Particle Experiment) to study low- and high-energetic particles in the magnetosphere with different sensors (Saito et al. 2021), **PWI** (Plasma Wave Investigation) to make a detailed analysis of the structure and dynamics of the magnetosphere (Kasaba et al. 2020), **MSASI** (Mercury Sodium Atmospheric Spectral Imager) to measure the abundance, distribution, and dynamics of sodium in Mercury's exosphere (Murakami et al. 2020), and **MDM** (Mercury Dust Monitor) to study the distribution of interplanetary dust in the orbit of Mercury (Kobayashi et al. 2020).

The name BepiColombo was given to the mission in honor of Professor Giuseppe (Bepi) Colombo (1920–1984) best known for his work on the planet Mercury. Colombo also explained Mercury's 3:2 spin-orbit resonance as a result of tidal forces of the Sun acting on Mercury, meaning that while Mercury orbits the Sun twice, it rotates around its own rotational axis exactly three times.

Overview

From dedicated orbits (Fig. 2), the two spacecraft will be studying Mercury, the planet and its environment. The mission will build on investigations done by the MESSENGER mission of NASA, which orbited Mercury for about 4 years from 2011 until 2015. BepiColombo will address a comprehensive set of scientific questions like:

- How has Mercury evolved and formed?
- Why is Mercury's density significantly higher than that of all other terrestrial planets?
- Is Mercury tectonically active today?
- Why does such a small planet possess a magnetic field?
- Is there any water or sulfur ice in the permanently shadowed craters at Mercury's polar regions?
- What are the production mechanisms of the exosphere?

BepiColombo, Fig. 2 Orbits of MPO and Mio. Both orbits are polar and elliptical with eccentricity and inclination optimized for the study of Mercury itself (MPO orbit: 480×1500 km) and its surrounding magnetospheric environment (Mio orbit: $590 \times 11,640$ km)

BepiColombo, Fig. 3 Exploded view of the BepiColombo spacecraft stack, which consists of four separate elements (ordered here from the bottom to the top of stack): (1) The Mercury Transfer Module, a ESA provided unit which carries an electric propulsion system to propel the stack to Mercury, (2) MPO led by ESA to study the planet surface and its interior, (3) the Sunshield and Interface Structure used to shield Mio during the cruise, and (4) Mio, the JAXA led Mercury Magnetospheric Orbiter to investigate Mercury's environment

•How does the magnetic field/magnetosphere interact with the solar wind?

•Can we take advantage of the proximity of the Sun to test general relativity with improved accuracy?and many more. In addition, it will provide information about Solar System evolution in general – not just about our own.

During its about 7-year long cruise phase to Mercury, the two science orbiter of BepiColombo, MPO and Mio, are carried by the ESA-built Mercury Transfer Module (Fig. 3). It contains the propulsion system and

will be jettisoned before the two orbiters entering their dedicated orbits at Mercury in late 2025 (Benkhoff et al. 2010, 2021).

Bernal's Conception of Origins of Life

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Keywords

Clays · Catalysis

History

John Desmond Bernal was a pioneer of diffraction X-ray method. His interest for biology increased during the 1930s and the 1940s, probably in relation with the study of biological molecules (peptides, nucleic acids, etc.) with this new physical method.

His work on the origin of life was marked by his first publication on this topic in 1951: a little book entitled *The Physical Basis of Life*, which came from a previous lecture (1947) and from a paper published in 1949 in the *Proceedings of the Physical Society*.

In this text, Bernal gave a synthesis of previous theories, that is, Oparin's (1924, 1938), Haldane's (1929), or Dauvillier's (1947) ones. Such as he claimed that primitive atmosphere of earth contained CO₂, he described the possibility of a progressive production of organic molecules and finally of life.

His main and original assumption regarded problems of dispersion and catalysis. Indeed, Bernal claimed that fundamental reactions could exist on clay deposits, marine, and freshwater, which could insure confinement and catalysis.

During the 1950s and 1960s, he actively participated in the scientific debates on the origin of life and was very active in the diffusion of ideas on the origin of life.

Fig. 1 Beta pictoris

Definition

Beta Pictoris b is a massive exoplanet directly detected around the A-star Beta Pic, on an orbit with a semimajor axis between 8 and 11 astronomical units. This is the smallest orbital distance known so far among the small set of exoplanets observed by direct imaging. The star which is at a distance of 20 pc (60 light years) is one of the best-known examples of a star surrounded by a dusty ► [debris disk](#). The disk was the first to be imaged and is now known to extend up to about 1,000 AU. The planet has a mass of about 9 Jupiter masses. It features the right mass and location to explain the observed warp in the inner parts of the disk (Fig. 1).

A team led by A.M. Lagrange used the NAOS-CONICA instrument, an ► [adaptive optics](#) corrected near-infrared imaging system mounted on one of the 8.2 m Unit Telescopes of ESO's Very Large Telescope (► [VLT](#)), to observe Beta Pic once in 2003 and then several times after 2008. On 2003 images, a faint source inside the

disk was seen, but it was not considered as a planet as it could have been a background star. On the images taken in 2008 and spring 2009, the source had disappeared, while in the observations taken during autumn 2009, and later, the object appeared on the other side of the disk after a time fully consistent with the object being an exoplanet orbiting its host star. The size of the orbit was also consistent with this hypothesis. Since then, the spectral energy distribution in the infrared was obtained which showed the planetary parameters to be fully consistent with the first evaluation of the orbit and mass (and pointed to a dusty planetary atmosphere at 1,700 K).

Because the host star is young (12 million years old), this discovery is considered as a strong indication that ► [gas giant planets](#) can form within protoplanetary disks in only a few million years, a short time compared, for instance, to the age of the solar system (4.5 Gyr).

The monitoring of the position of the planet was continuously done until today (2021) and for instance there has been an intense campaign in 2017 since the orbital analysis by Wang et al. (2016) showed that the star could pass within 10 to 20% of the radius of the Hill sphere of β Pic b, but nothing was detected. A second planet, Beta Pictoris c, was detected through radial velocity monitoring of the star (Lagrange et al. 2019) and confirmed thanks to observations with GRAVITY (Nowak et al. 2020; Lagrange et al. 2020). It orbits the star at a distance of 2.7 UA and its mass could be of 9 M.

Beta Rays

Jun-ichi Takahashi

Faculty of Engineering, Yokohama National University, Yokohama, Japan

Keywords

Beta decay · Chirality · Radioactive particles · Weak interaction

Synonyms

[Beta electrons](#)

Definition

A beta ray is a stream of beta particles (electrons or positrons). In nuclear physics, beta decay is a type of radioactive decay in which a beta particle is emitted.

Overview

In the case of electron emission, the decay is referred to as beta minus (β^-), while in the case of a positron emission as beta plus (β^+). In beta minus decay, a neutron is converted to a proton, an electron, and an antineutrino; in beta plus decay, a proton is converted to a neutron, a positron, and a neutrino:

If the proton and neutron are part of an atomic nucleus, these decay processes transmute one chemical element into another. Beta decay does not change the number of nucleons in the nucleus but changes only its charge. For example:

The kinetic energy of beta particles has a continuous spectrum ranging from 0 to maximal available energy, which depends on parent and daughter nuclear states participating in the decay. A typical maximal available energy is around 1 MeV, but it can range from a few keV to a few tens of MeV. The most energetic beta particles are ultra-relativistic, with speeds very close to the speed of light.

The spin of the electrons or positrons in beta rays is longitudinally polarized due to parity non-conservation in the weak interaction mediated by charged W particles. The helicity of a beta electron, that is, the spin angular momentum component of the kinetic momentum direction, is negative (left-handed), and that of a beta positron is positive (right-handed).

In the standpoint of astrobiology, one of the hypotheses for the origin of biomolecular chirality, the so-called cosmic scenario, states that asymmetric energy sources in space-induced asymmetric chemical reactions of precursors in interstellar dust, resulting in the enantiomeric excess of terrestrial bioorganic compounds. It has been proposed that beta rays are one of the candidates for the source of such asymmetric chemical reactions, which might lead to the origin of biomolecular chirality in terrestrial organic compounds.

Big Bang Nucleosynthesis

Alain Coc

IJCLab (Laboratoire Irène Joliot-Curie),
Université Paris-Saclay, Orsay, France

Keywords

Big bang · Nucleosynthesis · Helium ·
Deuterium · Lithium

Synonyms

BBN; [Primordial nucleosynthesis](#)

Definition

The nucleosynthetic process that took place within the first 20 min after the big bang is called big bang nucleosynthesis (BBN) or primordial nucleosynthesis. At this early epoch, the Universe was dense and hot enough to allow for nuclear reactions to take place, producing the “light elements,” ^4He , ^2H ($\equiv \text{D}$, i.e., deuterium), ^3He , and ^7Li , starting from neutrons and protons. The comparison between the primordial abundances of these isotopes deduced on one hand from observations and on the other hand from model calculations is one of the main support of the big bang model.

History

Prominent landmarks in the development of the big bang nucleosynthesis theory include works by Gamow in the 1940s (out of equilibrium nucleosynthesis in an expanding Universe dominated by radiation), Peebles in 1966 (big bang nucleosynthesis calculations up to ^4He), and Wagoner in 1973 (big bang nucleosynthesis calculations including ^7Li).

Overview

The big bang model is supported by three pieces of observational evidence: the expansion of the

Universe, the cosmic background radiation, and the primordial or big bang nucleosynthesis (BBN). Standard BBN is now a parameter-free model. The nuclear cross-sections and neutron lifetime, together with the number of neutrino families, have all been measured in the laboratory. The baryonic density of the Universe has been deduced from the observations of the anisotropies of the cosmic microwave background radiation (Aghanim et al. 2020). In the framework of an expanding Universe, with uniform temperature and density, decreasing with time, a temperature of 10^{11} K is reached a fraction of a second after the big bang. According to our present knowledge, the only particles present in the Universe at this time were photons, electrons, and positrons; the three families of neutrinos and antineutrinos, all in equivalent numbers; and a tiny fraction of neutrons and protons. Weak reactions (with electrons and neutrinos) maintained an equilibrium between the number of protons and neutrons until the Universe cooled down to $\approx 3 \times 10^9$ K. This occurred because the speed of weak force reactions became slower than the rate of space expansion. Consequently, the ratio of the number of neutrons to protons became frozen, except for free neutron decay. When the temperature dropped to $\approx 10^9$ K, the fusion of a proton and a neutron leading to a deuterium nucleus became favored compared to deuterium dissociation by high-energy photons. This was the starting point of primordial nucleosynthesis that stopped, after ≈ 20 min, with the formation of ${}^7\text{Li}$. This was caused by the decrease of density and temperature and lower nuclear cross-sections beyond mass seven (Coc et al. 2012). Hence, only the ${}^4\text{He}$, D, ${}^3\text{He}$, and ${}^7\text{Li}$ isotopes are significantly produced in standard BBN, involving a dozen main nuclear reactions. Despite the fact that the primordial abundances of these light isotopes span nine orders of magnitudes, the agreement between calculations (Pitrou et al. 2018; Fields et al. 2020; Mossa et al. 2020) and observations (Aver et al. 2015; Cooke et al. 2018; Bania et al. 2002; Sbordone et al. 2010) is good with the exception of ${}^7\text{Li}$ (but within a factor of ≈ 3). According to models, the big bang nucleosynthesis contributions to the solar system abundances, which

amount to $\approx 90\%$ for ${}^4\text{He}$, are uncertain for ${}^7\text{Li}$ and ${}^3\text{He}$ but are remarkably the only source of present-day deuterium.

Heavier elements, the building blocks of planets, are not significantly produced by BBN. For instance, the BBN production of carbon, nitrogen, and oxygen amounts to a total of $\approx 10^{-15}$ in the number of atoms relative to hydrogen (Coc et al. 2014).

Since all the parameters of the standard BBN model have now been measured, its abundance predictions reach the percent-level precision, at match with the precision on light element abundances deduced from observations. Hence, it can now be used as a probe of nonstandard physics in the early Universe (Iocco et al. 2009). However, the origin of the *cosmological lithium problem* (the factor of ≈ 3 difference between the ${}^7\text{Li}$ predictions and observations) is still a matter of debate (Fields 2011).

Bimolecular Reaction

Steven B. Charnley

Solar System Exploration Division, Code 691, Astrochemistry Laboratory, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Synonyms

[Two-body reaction](#)

Definition

A bimolecular reaction is a chemical process involving two reactants. Reactants may be electrons or

atoms and molecules existing in various combinations of charge states (neutral, anionic, or cationic). The most important reactant combinations for interstellar chemistry are ion-neutral, neutral-neutral, anion-neutral, electron-neutral, and electron-ion.

Binary Stars, Young

Steven W. Stahlner

Department of Astronomy, University of California, Berkeley, CA, USA

Keywords

Star formation

Definition

Most stars are not isolated objects, but have an orbiting companion. This basic fact holds not only for mature stars but also for objects at an earlier stage of evolution. Indeed, several young star clusters have a higher fraction of binaries than do main-sequence stars generally. Young binaries exhibit a very broad range in separations and therefore orbital periods. In the widest pairs, the orbits are highly eccentric. Conversely, the tightest pairs are locked into circular orbits. Planet-forming disks are absent in these latter systems, apparently because of the disturbing influence of the companion.

Overview

Astronomers have long known that most stars have binary partners, that is, companions locked gravitationally into orbit. About 60% of solar-type, main-sequence stars have at least one such companion. The vast majority of these

multiple systems are binaries, but triples and even quadruples also exist. Binarity is also common for stars of other spectral types.

Some binary companions are so close together that one can detect the induced wobble in the stars' motion, through a periodic Doppler shift in the wavelength of spectral lines. Such spectroscopic binaries are relatively rare. Most systems are discovered because the two stars share a common spatial motion. This implies that their pairing is physical and not a chance superposition. Overall, the observed range of periods is vast, from less than a day to millions of years, corresponding to separations from 0.01 to 10,000 AU.

The fact that most mature stars have companions naturally leads us to wonder if this situation held further back in time. Are ► [pre-main-sequence stars](#), those too young to fuse hydrogen into helium, also preferentially found in binaries? What about even younger objects, those still gathering mass from their parent molecular clouds? Since the 1980s, many researchers have investigated the matter, and the answer is now clear. Pre-main-sequence stars are also very likely to have a binary companion. Indeed, the binary fraction in some young clusters is even greater than for main-sequence stars in the field.

The systems being found show a wide range in orbital separations. Some are tight enough to be detected as spectroscopic binaries. Most young binaries, however, are noticed because they exhibit a common spatial velocity within their parent stellar group. On the whole, pre-main-sequence binaries span a wide range of separations and periods, just as do main-sequence systems.

Many individual pre-main-sequence stars have planet-forming disks, as evidenced by their excess infrared and millimeter emission. The same is true for stars within binaries, but with a significant caveat: if the binary separation is less than about 100 AU, corresponding to a period of about 1000 years, then the excess emission is absent. Apparently, the relatively nearby companion star prevents formation of any circumstellar disk. For periods as low as a few days, the primary and its companion are locked into perfectly circular orbits.

Binding Energy

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Binding energy is the energy required to disassemble an entity into its constituent parts. This corresponds to the mechanical work which must be done in acting against the forces which hold the entity together. The binding energy of an atom is that required to disassemble an atom into free electrons and a nucleus, acting against the electromagnetic force. The nuclear binding energy is that required to disassemble a nucleus into its constituent neutrons and protons, acting against the strong nuclear force. The term is also used in other contexts, for example, for the

energy involved in attaching a gaseous molecule to an ► [interstellar dust](#) grain upon collision. In this case, the magnitude depends on both the physical nature of the molecule (e.g., polarizability) and of the grain surface. Binding energies for ► [physisorption](#) (through van der Waals bonding) are generally much lower than those of ► [chemisorption](#).

Bioburden Controlled Environment

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

In planetary protection, a bioburden-controlled environment is an environment where the number of viable microorganisms, and therefore the potential for microbial contamination of space-flight hardware, is controlled or minimized. This includes clean rooms, laminar flow hoods or cabinets, and other temporary or permanent environments where the quantity of microorganisms and/or particulates is monitored and maintained below a specified level. Other characteristics of bioburden-controlled environments are the access controls on people and materials, and the use of clean room garments by operators in the bioburden-controlled environment, to prevent degradation of the cleanliness of the environment.

[Diversity of life](#)

Definition

Biodiversity designates the condition of life on Earth in terms of its variation at all levels of biological organization, from genes to ► [ecosystems](#). By extension, it is used to designate life on Earth itself, most generally at the ► [species](#) level but often also at all organization levels altogether. The political impact of the term led to a definition adopted by the International Convention on Biological Diversity (Art.2): “Biological diversity” means the variability among living organisms from all sources including, inter alia, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems” (Convention on Biological Diversity [1992](#)).

History

Although first introduced in the end of the 1960s, the word biodiversity, as a contraction of biological diversity, has been coined by Walter G. Rosen while preparing a national US scientific forum held in Washington in 1986. The objective of this forum was to discuss the importance of the quality and variety of living organisms in relation with the threats constituted by ► [environment](#) degradation, species extinction, and potential losses of socioeconomic benefits (Wilson [1988](#)). In parallel, the convergence of interest from the scientific community, from the nature conservation organizations, and from the southern countries, who want to control the economic benefit from their living resources, led the United Nations Environment Programme (UNEP) to explore the need for an international convention on biological diversity. This approach led to an international legal instrument for the conservation and sustainable use of biological diversity: the Convention on Biological Diversity was opened for signature on June 5, 1992, at the United Nations Conference on Environment and Development, better known as the Rio “Earth Summit,” and was adopted by 168 countries within the next year. In terms of

scientific organization and programming, an international research program on biodiversity, named *Diversitas*, was established in 1991 jointly by UNESCO, SCOPE (Scientific Committee on Problems of the Environment or the International Council of Scientific Unions), and the IUBS (International Union of Biological Sciences) to “promote an integrative biodiversity science, linking biological, ecological and social disciplines in an effort to produce socially relevant new knowledge; and provide the scientific basis for the conservation and sustainable use of biodiversity.” Ten years after Rio, the second Earth Summit held in Johannesburg in 2002 set the so-called 2010 target: “to achieve by 2010 a significant reduction of the current rate of biodiversity loss at the global, regional and national level as a contribution to poverty alleviation and to the benefit of all life on Earth.” Clearly the target has not been met, in the absence of instruments of measure as well as of effective policies.

However, the conjunction of scientific interest and social pressures has modified how ecologists, taxonomists, population geneticists, paleontologists, and social scientists of environment situate their own disciplines, toward an integrated vision where most see themselves as contributors to biodiversity research.

Overview

Biodiversity science is above all integrative. The central problem of biodiversity research is to understand how diversity of life, that is, the variation in quality *and* quantities of living things at any scale, relates to the functioning and evolution of ecosystems including the human populations and societies. In consequence, all population-level research may be relevant at any scale, from any local group of living organisms to all past, present, and future life. Taxonomists (or systematists, including paleontologists) explore and describe the patterns of biodiversity, present and past, proposing scenarios illustrating “how” – in terms of a suite of inferred historical events – biodiversity reached its present state at

the largest scales. Evolutionary biologists aim at understanding “how” – in terms of biological processes – biodiversity reached its present state at genetic and population levels. Ecologists explore the patterns of species interactions in ecosystems and the mechanisms of ecosystem functioning; and social scientists explore the relationships between human populations and societies and nonhuman biodiversity. Focus on socioeconomic benefits, which were already encompassed by the initial thoughts in the 1980s, has brought emphasis of the concept of ecosystem services, that is, the part of the ecosystem functions and products that is used by our species.

We understood as late as in the 1980s that the number of living species is probably tenfold the previous estimates, in the 10–40 million living species range, rather than 1–2 million (Erwin 1982 and subsequent papers). In parallel, it has become progressively evident that unprecedented losses and changes in biological diversity are taking place at the genetic, species, and ecosystem levels, particularly in nonmarine groups of organisms so far. Comparison with major extinction crises in the geological history of the Earth reveals that the current rate of extinction is at least in the same order of magnitude and several hundred times greater than the average between crises (Dirzo and Raven 2003). The present extinction crisis does not strike us because it is not catastrophic at the scale of the human lifespan, but rather in a time span of several millennia, which we do not perceive directly but is still a very short instant in the more than 3.5 billion year-long history of life on Earth. This crisis, sometimes referred to as the Sixth Extinction, is likely the direct result of human activities.

Understanding the patterns and processes of biodiversity loss and change is crucial for our species, not only because of the aesthetic, ethical, or cultural values attached to biodiversity but also because it could have numerous far-reaching consequences for our own life-support system. Even the chemical composition of the air we breathe and of seawater depends upon biological activity well beyond the increase of carbon dioxide in the

atmosphere and of acidity in the seawater, which results directly from human activities.

One of the likely consequences of man-induced changes in the environment is the reduction in the capacity of natural and managed ecosystems to deliver ecological services, such as the production of food and fiber, carbon storage, nutrient cycling and resistance to climate, and other environmental changes. Assessing the causes and consequences of biodiversity changes and establishing the bases for the conservation and sustainable use of biodiversity are major scientific challenges of our time. The major questions that research is facing are summarized in the *Diversitas* research program (Diversitas 2002, 2010).

How Did Biodiversity Evolve in Space and Time to Reach the Current State?

There are two kinds of sciences answering the “how” questions. The first one is focusing on the biological processes by which living matter diversifies its forms (see the entry *Evolution* (biological)). The way these scientists demonstrate their statements is close to that of chemistry or physics. By manipulating populations of organisms with very short generation times, it is possible to develop a hypothetico-deductive experimental approach to these “how” questions: population genetics is of first importance in the field. But there are also other experimental sciences like causal embryology or physiology that participate to the understanding of this “how,” though without any population approach.

The second approach is the historical “how.” A set of sciences like descriptive and comparative embryology and anatomy, paleontology, and systematics participate in a historical interpretation of how life arrived to its present state. The present distribution of organisms is explained by a suite or series of events, not necessarily linked to each other by causal relations. ► **Phylogeny** provides part of the information needed for the ordering of events through time. Other data, paleontological, stratigraphical, geological, etc., also participate in our knowledge of the history of biodiversity. The answer to the historical “how” has made decisive

progress in the last two decades through the association of the phylogenetic method introduced by Willi Hennig (Hennig 1966) with informatics and use of DNA sequences: phyloinformatics now allows processing large data sets, whether molecular or morpho-anatomical. Thanks to phylogenetic methods applied to molecular characters, our vision of the tree of life has been radically modified within the last 25 years and is still evolving. Within 25 years, our vision of the tree of life has shifted from five “kingdoms” to three main branches or clades, of which two are bacteria domains diverging from each other just as much as from ours, the eukaryotes (the organisms constituted by one to many cells with a nucleus). Convincing evidence has been brought to explain the origin of eukaryotes by multiple bacterial endosymbioses: our own cells, their mitochondria, and plasmids originate indeed from as many bacterial lineages. It is now admitted that lateral ► **gene** transfer (i.e., gene transmission between two otherwise independent lineages) is a relatively frequent phenomenon at least in bacteria and may well influence significantly their evolution.

At the ecosystem level, “how” is also a question from both points of view: from an ecological processes point of view, not only chance, that is, the initial conditions, but also species interactions doubtless shape the local communities in time, even though we are hardly able to understand and even less to predict the change when more than very few species interact. The historical “how” may be easier to grasp, thanks to both paleontological observations and, possibly, by combining the phylogeny of the species composing a community with the composition of the latter through time. An objective is to relate ecosystem change with causal factors such as climate change, entry of a clade into a new region, or the origin of innovations in a clade.

How Much Biodiversity Exists and How Does Its Change or Loss Affect the System as a Whole?

A prerequisite to the “how” is the “what,” that is, documenting biodiversity. Understanding how

little we know about the existing species implies that traditional methods and techniques are inappropriate, and new strategies are developed to increase the efficiency of field sampling, the quality and accessibility of collections for fieldwork, the collection and curation of voucher specimens, the technologies for imaging and DNA sequencing, the digitization of legacy data, and the development, maintenance, and connectivity of relevant databases. The need for rapid-capture technologies for identifying known species and discovering new ones has led to the development of the “Barcode of Life” initiative, which aims at providing IT tools for identifying species through short DNA sequences obtained from specimens identified by an expert and kept in legacy collections (Consortium Barcode of Life 2010; Golding et al. 2009). The need for access to the information on species occurrences and on the collections, which may well soon include the only remaining specimens of many species in view of the current rate of extinctions, has led to the constitution of the so-called GBIF (Global Biodiversity Information Facility 2010; Edwards et al. 2000), which is an international informatics infrastructure that allows the interoperability of the innumerable databases on collection specimens and species occurrences worldwide.

A serious problem for assessing species diversity is the uneven distribution of expertise among taxa and countries: groups of very high diversity and ecological importance, such as nematode worms, acarians, most insects, or microbes, in general, are notoriously understudied and very poorly known, whereas groups that are closer to us in terms of body organization, size, and appeal to imagination may even have more specialists than species, as is the case of birds or elephants. In parallel, expertise is located mainly in Western developed countries, principally in Europe and North America, whereas most megadiverse tropical countries have very few specialists and insufficient research infrastructures: biodiversity is in the South but expertise and infrastructures are in the North.

For their own biodiversity assessments and in response to the environmental concerns, which

are at the origin of environmental regulations, rich countries have developed observation networks that are feeding large observational databases, managing billions of observational data. These databases provide the basic tool for the application of environmental regulations regarding species and habitats but also constitute a tool for research when standardized and made interoperable, *inter alia*, thanks to the GBIF. Their weakness is that they necessarily concentrate on taxa for which there are a number of observers, that is, principally higher plants and vertebrates. However, when enough data have been collected in the medium and long term, it has been possible to show such phenomena as the decline of populations of common birds in Europe or the shift in distribution toward the north of bird and plant species as a consequence of global warming. In the domain of fisheries, fishing data collected since the end of the nineteenth century have allowed us to show that overfishing started at least more than one century ago, leading to constant diminution of tonnage and size of the fish at the world level and unpredictable consequences over the food web and equilibrium of the global ocean.

However, assessing is not enough in both scientific and societal terms: we want to be able to predict the change, for scientific reasons as well as for decision making in environmental policy. The solution lies in modeling, operationally based so far upon statistics on species distribution in terms of environmental parameters. This approach, called niche modeling, allows one to calculate an ecological envelope that can be projected on a map to delimit species' potential distribution in space. It is then easy to modify some environmental parameters, including climatic ones, to predict the consequences of changes on species occurrences and, to some extent, on the composition of communities. This approach has proved very powerful to define policies and strategies regarding invasive pest species in Mexico or the design of protected areas; but it is somewhat rudimentary by not taking into account ecological structures and processes, nor metapopulation dynamics, habitat fragmentation, etc. The ultimate goal is not just to understand but to predict biodiversity change, developing biodiversity scenarios that

predict biodiversity change at the landscape, regional, and global scales in response to various scenarios of how anthropogenic drivers will change in the future.

How Does Biodiversity Correspond to the Delivery of Ecosystem Functions and Services and What Is the True Value of These Commodities?

Over two decades of research in ecology have shown that the combination of abiotic (physical and chemical) factors together with biological interactions determines the limit of biodiversity in a community and that the composition of this community influences, in turn, the way it functions. A large number of experiments since the beginning of the 1990s have confirmed that generally the increase in biodiversity has a positive effect on ecosystem functioning.

Three mechanisms have been proposed to explain this positive effect. The first is a simple sampling effect: species-rich ecosystems would produce more biomass, simply because the probability for including a highly productive species is higher as the number of species is increased. The second is the functional complementarity of species resulting from a favorable pattern of traits in the community: by increasing diversity, one increases the number of effective ecological functions as more ecological niches are exploited. For example, two plant species having different root lengths extending down to the ground will better exploit resources in the soil and then produce more biomass together, than a single of them. Finally, interaction of two species, then called facilitation, may have a positive effect on production: for example, brambles in a meadow may create favorable conditions for smaller species that need moisture and shade, such as arum lilies, and doing so favors the increase in productivity of the system.

These mechanisms may be effective at any time and space scale, from bacteria and fungi in a piece of cheese to the entire tropical forests and oceans. However, for practical reasons, most experiments have been based on plant communities, including the two best known, the European BIODEPTH and the American Cedar Creek

experiments, which both have shown a positive effect of diversity upon biomass accumulation in the communities.

The relationship between diversity and stability of ecological communities has also been studied, showing at least theoretically that some species may have a key role for the persistence of the community when facing environmental disruption: roughly, having more species increases the chance of having at least one or a few able to develop under modified conditions and in so doing allow persistence of the community. Few experiments have tested this conclusion, but these few confirm so far the theoretical prediction of a relation between diversity and stability of ecosystem functioning.

However, most experiments neglect the trophic relationships between species, which we know are very complex in species-rich ecosystems, from predation and parasitism to mutual dependence such as in pollination processes. A starting point may be the top-down effect, through which a predator controls the density of prey, which themselves control production at lower trophic levels. Diminution in density at the top levels may allow an indirect increase in production at the lowest levels; but it may also have just the opposite effect when top levels participate significantly in nutrient recycling, which itself increases productivity: this may well be what happens as mankind clearly exploits and overexploits large predators.

Overall, we know now that diversity favors ecosystem resilience and biomass production. It is also suspected that diversity favors diversity. An illustration of this is, for example, the recent discovery of very high levels of horizontal or lateral transfers of DNA in microbial communities, in a way that genomes exhibit functional-environmental patterns as well as historical patterns. Horizontal heritage is far more important than previously thought, compared to “classical” vertical heritage. These networks of permanent DNA exchanges among a diversity of microbial “species” in a given environment (either marine, lacustrine, or terrestrial) stabilize the role played by these environmental communities in the biosphere. Generally speaking, the question of positive feedback of diversity is fundamental in

view of the present changes in ecosystems and still requires further research at various levels of ecosystem organization. If it is true, human activities endanger self-regulation of ecosystems, of which many are at risk of collapsing with unavoidably serious risk for our own species.

How Can Scientific Investigation Support Policy and Decision Making to Encourage More Sustainable Use of Biodiversity?

In view of the societal needs for a better understanding of the functions of biodiversity for human beings (and well-being where possible), communicating scientific results to relevant political levels is crucial. Researchers are trained in research and communication with other researchers, but not in communication toward decision makers, which results in numerous misunderstandings. This renders the formation of an ad hoc mechanism a necessity. Based on the example of the IPCC (Intergovernmental Panel on Climate Change), the United Nations and the G8 have endorsed in 2010 the creation of such a mechanism, called the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES 2010; Larigauderie and Mooney 2010) as initially proposed by France in 2005. The IPBES progresses at an intergovernmental pace, which is slower than species extinctions and ecosystem change, but will hopefully allow progress in the implementation of the necessary policies.

Key Research Findings

Since the beginning of the 1980s, a few points have been understood:

- First is a revolution in our vision of the tree of life and of the origin and diversification of eukaryotes. All eukaryotes are no more nor less than each of the two main “prokaryotic” clades (Bacteria and Archaea), fungi and animals now appear as originating from a common ancestor not shared with other groups, and humans are nothing more than the tip of a tiny twig among all mammals, which occupy

nothing more than a small branch of the small clade constituted by all animals in the tree of life.

- Next is the change of paradigm in both taxonomy and ecology: we now know that we know nothing about most living species and that the way we interact with biodiversity is not sustainable for the present ecosystems at any level, whether marine or land based.
- The whole biosphere is changing at all levels, possibly faster than ever, and surely through a process without precedent, which is provoked by our species: destruction of whole ecosystems and modification of others through anthropic activities including transport of species are realities that we have to face.
- In scientific terms, we understand better how biodiversity acts in the functioning of the whole ecosystems: biodiversity favors both production and stability of ecosystems and likely has a positive feedback on diversity itself.

Future Directions

On the purely scientific point of view, the main future direction to maintain our understanding of biodiversity is to keep all contributing sciences visible at the political level. The study of biodiversity is not merely a matter of counting the species that are found in a given area or proposing models predicting responses of ecosystems to anthropic perturbations. The future in studies and understanding of biodiversity must keep systematics and evolutionary biology as central disciplines along with inventories and ecological modeling.

Systematics is important in understanding the reasons why we classify living and fossil organisms as we do. Systematics provides the reason why the platypus is classified well apart among mammals. Phylogenetic systematics explains why the collection of traits exhibited by the platypus is so unique. If a decision has to be made concerning the preservation of the platypus, the ecological role of the platypus is going to have a negligible

weight compared to the argument from systematics. The platypus (or the coelacanth, choose the one you prefer) is negligible in terms of biomass, and its role in its environment could be replaced by another imported species. In terms of what organisms do in their environment, the platypus (or the coelacanth) can perfectly well be sacrificed. By contrast, phylogenetic systematics will provide the arguments to regard this species as a very important one. Phylogeny will show that the platypus is the product of a very ancient mammal lineage represented today by three species only. The characters exhibited by the platypus show this: it lays eggs and it has a bizarre anatomy of the temporal area. In parallel, the lineage gained characters on its own branch, such as a duck-like beak or venomous fangs on the posterior limbs. The combination of the whole set of properties makes the platypus a kind of unique evolutionary heritage – a rare combination of characters. Protecting species should therefore be considered in terms of what they *have* (systematics), not only through what they *do* (ecology).

Evolutionary biology is also important because we cannot pretend to understand and properly protect biodiversity without having a deep knowledge of the processes that generate biological diversity at all levels. This is going to be important because it is not sufficient to save the present state of nature as if it would not be going to change again. Life is continuously changing. It is important to protect the potential ability to get adapted to new conditions, so maintaining genetic variability and our knowledge about processes that generate it (and select it afterward) is of key importance.

The second relevant direction for our knowledge and action is to consider human societies and their products as parts of biodiversity. There is a philosophical tradition that keeps humankind separated from an undefined nonhuman “nature” or an undefined category of “animal” and that keeps culture separated from nature. In contrast, we are not only trying to change the world to save the diversity of this wonderful life but also to save the cultural-material heritage for the few next human generations.

Although the economics of biodiversity is a rapidly expanding field, and understanding the relationship between biodiversity and ecosystem functioning is still seen as a research priority, for practical reasons focus is presently made on observations and monitoring. Not only scientists but also all kinds of decision and policy makers need reliable information on what is happening and projections of what may happen, both locally and globally. Decreases of coral reefs and more generally ecological consequences of acidification of the oceans, changes in the composition of the atmosphere, invasion of exotic species, changes in the species distribution resulting from climate warming and transportation by humans, and destruction of habitats under anthropogenic pressures are all happening and hardly evaluated due to the lack of appropriate instruments. This observation calls for at least two lines for action from the scientific community:

- The first one is improving our capacity for the analysis and prediction of the change in biodiversity. Operational models based upon niche modeling that are already in use to assist decisions should be developed further. The predictive value of models could doubtless still be improved by incorporation of ecosystem functional parameters, as ambited by many ecologists; however, this development is impeded so far by the weakness of the concepts relating to ecosystem functions, which still requires a qualitative jump forward.
- Complementary and necessary for development of modeling is documenting what occurs and what happens, because without reliable data we may hardly hope to understand what is happening globally. Even local predictions require global data sets because, like in meteorology, operational modeling is based upon statistical approaches of which precision and reliability are in proportion to the amount of observations available. This need for data and monitoring is taken into account by the projected construction of the Global Earth Observation Biodiversity Observation Network (GEO BON), which is a

program for the coordination of observations on biodiversity promoted by Diversitas. GEO BON is a component of the Global Earth Observation System of Systems (GEOSS), an initiative led by the World Meteorological Organization (Scholes et al. 2008).

Clearly, biodiversity research is shifting from traditional fundamental questions on what is there, why it is there, and how it works to questions relating directly to societal concerns guided by the central question of where mankind is going in a context of radical ecological change at the global scale. So far, this shift is beneficial rather than detrimental to fundamental research; and indeed the questions raised by society regarding its own future as a constituent of biodiversity will not find their answers if progress is not going on in fundamental ecology, systematics, and evolutionary biology.

To conclude on a positive note, we are right to be concerned by the ongoing Sixth Extinction. However, life has to be considered in the very long term. The Sixth Extinction is a problem of our responsibility for the next 2 to some 200 human generations, but it is not a problem for life itself. Several drastic extinctions have taken place in the past million years; there will be others. Our theoretical framework allows us to predict that biodiversity will be recovered, as rich as ever or more, and life and Earth will continue to change together as time will continue going by.

Biodiversity (Planetary Protection)

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

For ► [planetary protection](#), the biological diversity (biodiversity) in an environment is the inventory of types of ► [microorganisms](#) identified as being present. For microorganisms, the

identification depends also on the sensitivity and specificity of the ► [assay](#) which is used. For example, to prepare future missions to ► [Mars](#), space agencies are conducting studies in the clean rooms used for spacecraft assembly to establish the biodiversity of the spacecraft being built there.

Definition

Bioenergetics is the part of biochemistry dealing with ► [energy](#) flow through living systems. Life is dependent on energy transformation reactions. The ability to harness energy from a variety of metabolic pathways is a property of all living organisms.

Overview

Life and Energy

Life implies work. All life systems perform work: chemical work is needed for the synthesis of macromolecules, osmotic work is required for the maintenance of cellular concentrations, and

electrical work is necessary for the generation of ► **proton motive force**. Energy is the capacity to do work. Until the principle of the conservation of energy, the first law of thermodynamics, was enunciated in the middle of the nineteenth century, progress in bioenergetics was extremely slow.

The second law of thermodynamics establishes that in an isolated system, entropy (a measure of molecular disorder) can never decrease. The second law was enunciated for inanimate matter; however, a violation of this principle by living organisms has never been observed. Therefore, on empirical grounds, the validity of the second and first laws of thermodynamics for living organisms is generally accepted. Nevertheless, it must be kept in mind that living beings are open systems.

Not all processes permitted by the second law of thermodynamics can be used by living systems, for example, they cannot use the differences in temperature generated by combustion. The source of energy to perform biological work is chemical, and only few classes of chemical reactions can be used for these purposes.

The Earth is in a steady state. The intake of energy is just compensated by its loss. Energy intake and energy loss occur entirely through radiation. In a steady state, the entropy content of the Earth must be also constant. Entropy is gained in the form of solar radiation and loss as electromagnetic radiation. Entropy is also produced through irreversible processes. The rate of production of entropy must be equal to the net loss. Thus, in balance, the Earth emits entropy, and this entropic compensation is also operative in the biosphere. While organisms give just as much energy as they gain, the entropy associated with the energy released must exceed the entropy associated with the energy taken up. Organisms can develop if they interpose themselves into a gradient of entropy between incoming and outgoing energies.

Entropy is absorbed by live systems in the form of chemical substrates and radiation. In a chemical process, in ideal conditions, the sum of the entropies of the reacting chemical system and the environment remains constant all the time. In ideal

conditions, the process is carried out reversibly, but a small change in the parameters, for example, concentration, could reverse the direction of the process.

In living systems, work generated from chemical substrates is not produced by way of heat. Chemical energy is transformed into other forms of energy (e.g., ► **Proton Motive Force**, ► **ATP**) without passing through a heat stage. The small gradients of temperature that might exist within organisms are never used for work. In general, live systems work isothermally and isobarically.

In bioenergetics, the concept of free energy is very useful. The molar free energy, G , is defined as

$$G = H - TS$$

where H is the molar energy content, T is the temperature, and S the molar entropy content. Strictly, in an isobaric system, H should be called enthalpy and G free enthalpy. But in isobaric conditions, the volume changes are so small that the difference between enthalpy and energy disappears. The energetics of the reaction can be described in terms of the differences between products and reactants as

$$\Delta G = \Delta H - T\Delta S$$

The free enthalpy change ΔG has a negative value when the reaction is written in the direction in which it proceeds spontaneously, i.e., an exergonic reaction. In the opposite direction, the reaction is endergonic, and not spontaneous. The maximum work that can be obtained from a chemical reaction is given by ΔG , and it is obtained when the reaction is performed reversibly. But when a reaction has an irreversible component, some of the energy is dissipated as heat and then additional entropy is generated. While ΔH is mostly measured by calorimetry, ΔG and $T\Delta S$ are normally derived from measurements of chemical equilibrium. ΔG is related with the equilibrium concentrations of products ($c_{p1}, c_{p2}, \dots$) and reactants ($c_{r1}, c_{r2}, \dots$) and their actual concentrations ($c_{p1}^*, c_{p2}^*, \dots, c_{r1}^*, c_{r2}^*, \dots$):

$$\Delta G = -RT \ln \frac{c_{p1} c_{p2} \dots}{c_{r1} c_{r2} \dots} + RT \ln \frac{c_{p1}^* c_{p2}^* \dots}{c_{r1}^* c_{r2}^* \dots}$$

provided that activities can be replaced by concentrations. For physicochemical standard conditions (pH value 0), the value ΔG is called ΔG° . For physiological standard conditions (pH value 7), ΔG is by definition $\Delta G^{\circ'}$.

The equilibrium constant K is defined as

$$K = \frac{c_{p1} c_{p2} \dots}{c_{r1} c_{r2} \dots}$$

Therefore, for standard conditions,

$$\Delta G^\circ = -RT \ln K$$

and

$$\Delta G^{\circ'} = -RT \ln K'$$

As ΔG° (or $\Delta G^{\circ'}$) is a measure of the tendency for a reaction to occur in standard conditions, it is also known as the reaction affinity. The greater the affinity, the more exergonic the reaction and the more negative ΔG° (or $\Delta G^{\circ'}$). It has to be underlined that the exergonicity or endergonicity of a reaction, in a given condition, is not determined by the standard values (ΔG° or $\Delta G^{\circ'}$) but the values of ΔG . The work obtainable from a reaction is influenced by the actual concentrations, more exactly activities, of the reactants and the products.

As mentioned in the ideal case of reversible reactions, no entropy is generated. However, reactions cannot proceed fully reversible if they have finite velocities. Metabolism cannot be too slow. Therefore, full reversibility cannot be attained and entropy must be generated. Hence, entropy is certainly generated when organisms do external work.

Experimental work shows that antagonistic catabolic and anabolic processes always proceed along different pathways. Catabolic reactions are usually exergonic; thus, the corresponding anabolic reactions cannot proceed spontaneously, at least not in the same conditions. Therefore,

different pathways, which proceed at the expense of additional energy, are used for anabolism. In general, more energy in useful form is needed for anabolism than the energy obtained in catabolism. Often, no useful energy is obtained at all in the catabolic reactions of dynamic states. In this case, energy is dissipated as heat.

Active Transport

One of the most important dynamic states of the cell is the so-called active transport. Active transport is related with the transport of molecules and ions across the ► [cell membrane](#) against a concentration gradient. It requires osmotic work. To perform osmotic work, free energy is required. When the concentration of a solute in one side of the membrane is different from the concentration in the other side, diffusion to equilibrate the concentrations in both sides of the membrane occurs. The direction of the transport is given by the change in free energy:

$$\Delta G = RT \ln \frac{a_2}{a_1}$$

a being the thermodynamic activity, which as we mentioned before in most cases can be approximated to concentration. In diffusion ΔG is negative. In active transport ΔG is positive; this is the reason why osmotic work must operate to allow the solute to cross the membrane against a concentration gradient. If the solutes have a charge (ions), then an additional term related with the electrical potential must be considered.

Through active transport, large differences in concentration of molecules (i.e., glucose) and ions (i.e., H^+ , Na^+) can be set up between the cytoplasm and the environment or between different cell compartments in eukaryotic cells. Obviously if a difference in concentration across the membrane is generated by active transport, diffusion will operate in the opposite direction; thus, work must be performed all the time to maintain a steady state. Solutes are pumped across the membrane by specific mechanisms. Specificity is extremely important in active transport to ensure that the cell invests energy in transporting useful compounds. As has been pointed out, dynamic

states are very important for life systems. No organism is known to be able to develop without dynamic states. The complex mechanisms to maintain and regulate dynamic states are rather universal. One of the biggest surprises that is emerging from the analysis of whole-genome sequences is the high percentage of genomic information devoted to active transport, which underlines its importance.

Active transport is also the basis of cell bioenergetics. Most ► [energy conservation](#) reactions are directly or indirectly related with active transport systems. From an energetic point of view, active transport can be classified as transport reactions that generate useful energy for the cell (primary active transport) and those that require energy for its functioning (secondary active transport). Examples of primary active transport are ► [respiration](#), ► [photosynthesis](#), the transport of the fermentation products, and the ► [ATPase](#) activity, all of them coupled to the generation of ► [proton motive force](#). Examples of secondary active transport are the transport of nutrients to the cell, the maintenance of homeostatic ionic concentrations inside and outside of the cell, the bacterial flagellar movement produced, and the synthesis of ATP, all of them coupled to the dissipation of the ► [proton motive force](#).

In respiration (see ► [Respiration](#)), an electron donor gives electrons to an appropriated electron acceptor through the use of an electron transport chain located in the ► [cell membrane](#) in prokaryotes and in the mitochondrial membrane in eukaryotes. The passage of electrons through the chain promotes the translocation of protons, generating a gradient of protons between both sides of the membrane. The difference in potential energy (chemical energy) between the electron donor and the acceptor is transformed in proton motive force, a universal storage system of cellular energy.

In ► [photosynthesis](#), the photosynthetic reaction center is excited (oxidized) by radiation, and the excited electron is trapped by a constituent of an associated electron transport chain, and as in the respiration, the passage of the excited electron through the different components of the chain can promote (i) the translocation of protons producing

a gradient of protons (proton motive force) or (ii) the generation of cellular reducing power, depending of the type of photosynthesis. In the first case, the same excited electron goes back to the oxidized reaction center to reduce it to the ground state (cyclic ► [anoxygenic photosynthesis](#)). In the second case, an electron donor must donate an electron to the reaction center to bring it to the ground state (oxygenic photosynthesis, noncyclic anoxygenic photosynthesis), getting in both cases ready for another excitation reaction using radiative energy. In the photosynthesis, the source of energy is radiation and is transformed through a more or less complex system (depending on the type of photosynthesis) in cellular energy (proton motive force and/or reducing power).

Fermentation is the only bioenergetic system that does not make use of an electron transport chain to conserve energy (see ► [Fermentation](#)); instead cytoplasmic soluble enzymatic reactions are able to generate cellular useful energy (ATP) from chemical energy (reduced carbon substrates). Interestingly enough, because fermentation is the main source of energy for these organisms, an important amount of substrate must be fermented for growth, and as a consequence, a high concentration of fermentation products are produced (i.e., ethanol, organic acids). If the organism is able to couple the translocation of the fermentation products to the generation of a proton gradient, then the potential energy stored as a concentration gradient of fermentation products, which is not useful to fuel energy requiring cellular reactions, is transformed in proton motive force, a useful cellular energy source. In the absence of coupling between both transports, only diffusion applies and the potential energy is lost. It has been calculated that up to one third of the cellular energy used by fermentation organisms can be generated by this peculiar active transport system.

All these are examples of primary active transport systems because they can transform different ► [energy sources](#) in proton motive force. Once there is enough energy stored as proton motive force, it can be used to promote reactions that require work. The best-known example is the

translocation of cellular substrates (i.e., glucose) to the interior of the cell against a concentration gradient. Normally, organisms, especially prokaryotes, live in habitats with extremely low concentration of useful substrates to obtain energy. The required concentrations of these substrates inside the cell for metabolic reactions to proceed are several orders of magnitude higher than their concentration in the environment. Thus, very active transport system is required to concentrate these substrates inside the cell. To do this osmotic work, energy in the form of proton motive force is used. In this case, the translocation of a specific substrate is coupled to the dissipation (transport) of proton motive force.

Similarly, proton motive force can be used to maintain a high concentration of K^+ or a low concentration of Na^+ inside the cell. Due to simple diffusion, the high concentration of potassium stored inside the cell and required for an optimal performance of the different functional enzymatic activities leaks out because the concentration of this cation is rather low outside of the cells. To maintain a high concentration of potassium in the cytoplasm, an active transport is required, because it has to be performed against a concentration gradient. The coupling between the translocation of potassium to the interior of the cell with the dissipation of the proton motive force allows maintaining the optimal cellular potassium concentration. A similar situation can be found with the sodium concentration. In this case, the optimal cellular condition is a lower concentration of this cation in the cytoplasm than in the environment. In this case, simple diffusion leaks sodium to the cytoplasm, so the active transport required to pump sodium out of the cell can be performed using the energy stored as proton motive force through the coupling of both transport systems.

But energy stored in the form of proton motive force can be used for other cellular functions different than transport, like the bacterial movement of flagella. In this case the dissipation of the proton motive force is used to perform a mechanical work: the rotation of the flagella or the reverse transport of electrons in the electron transport chain to generate reducing power for

microorganisms that need it and cannot produce it by other means (many chemolithoautotrophs).

A special case of active transport that requires attention is related with a membrane enzymatic complex involved in the synthesis and hydrolysis of ATP (see ► [ATPase](#) and ► [ATP Synthase](#)). The membrane-bound synthesis of ATP from ADP and phosphate is an endergonic reaction that requires energy. This reaction, named ► [ATP synthase](#), can be fuelled by the use of the energy stored as proton motive force. In this case, it will perform as a secondary active transport system. But the same enzymatic complex can perform in the opposite direction: hydrolyzing ATP and using the released energy to promote the translocation of protons outside the membrane, generating proton motive force. In this case it is performing as a primary active transport system. The reversibility of this reaction is the core of the bioenergetic regulation of prokaryotic cells. Experimentally, it can be shown that there is a linear relationship between the intracellular concentration of ATP and the proton motive force. If the proton motive force measured as membrane potential corresponds to the concentration of ATP measured inside the cell, no activity can be detected. If the proton motive force is lower than the value that will correspond to a given concentration of ATP, then ATP is hydrolyzed to generate proton motive force until both systems are equilibrated. If the proton motive force is higher than the value that should correspond to the ATP concentration, then the proton motive force is dissipated to increase the ATP concentration until both systems reach equilibrium. With only one metabolic activity, prokaryotes can regulate in an efficient manner and with little genomic investment the bioenergetics of the cell.

Synonyms

[Microbial mats](#); [Periphyton](#)

Definition

Biofilm is a layer of microorganism(s) or microbial communities growing on a solid surface, usually of thicknesses ranging between several μm to

Biofilm, Fig. 1 Biofilms in the acidic waters of Río Tinto, SW Spain

several mm. The thicker biofilms are also referred as ► [microbial mats](#).

Overview

Biofilm communities are found in various aquatic and subaerial ecosystems or even in the human body (e.g., dental plaque) at liquid-solid or aerial-solid interfaces (Fig. 1). Typical biofilms develop on stones in streams and rivers or at the bottom of lakes. They participate in nutrient and energy cycling in the given ► [ecosystem](#) and could serve as a substrate for colonization by other species. Repeated sedimentation of inorganic material on the growing biofilm leads to layered structure resembling stromatolites (Krumbein et al. 2003).

Biofilms are usually formed by various microorganisms that include autotrophs as well as heterotrophs, eukaryotes, bacteria, and, in the most extreme conditions, archaea (Aguilera et al. 2007a). The organization level of the

Biofilm, Fig. 2 Example of a photosynthetic biofilm consisting in the association of unicellular red alga *Cyanidium caldarium*, filamentous green alga *Klebsormidium* sp., and pennate diatom *Pinnularia* sp. from Río Tinto, Spain

biofilm species can range from unicellular flagellates to multicellular filaments (Fig. 2). If the biofilm is formed by several layers of microorganisms, gradients of physical and chemical factors (e.g., light, pH, O₂) are established and influence its structure and species composition. The microenvironment within the mature biofilm could be different from that of the surroundings and could provide protection to more sensitive species (Ferris et al. 2005). For example, acidophilic red alga *Cyanidium* sp. is more tolerant to pH values above 3 than to those below 1, probably due to adaptation to elevated pH in biofilm interior (Kvíděrová 2012). It is possible that microorganisms within biofilms communicate by chemical signals. Such communication has been detected in biofilms of pathogenic bacteria, but in natural communities very little is known of this phenomena (Kellner and Surette 2006).

The development of a biofilm starts by accumulation of amorphous particles containing inorganic grains and bacteria. The cells divide, produce extracellular polymeric substances, form microcolonies, and provide substrate for further colonization by fungi and small eukaryotic heterotrophs like amoebas. The flagellates also participate at the initial formation. The sessile genera are observed later and could

require establishment of some organic matrix to be attached on. Filamentous microorganisms are last to appear. Small pieces of mature biofilm detach either due to internal signals or external factors, like water flow, and could colonize a new surface (Aguilera et al. 2007b).

Biofilms are the new microbial ecology frontier. Biofilms have not been studied in a systematic way until recently due to lack of appropriate methodologies. Confocal microscopy and in situ hybridization techniques allow to study intact biofilms and appreciate their complex structural diversity. For evaluation of photochemical performance of autotrophic biofilms, methods using variable chlorophyll fluorescence are applied in field (Gómez et al. 2011; Marteinson et al. 2013) and in detailed laboratory (Kvíderová 2012) studies.

An important part of microbial life on Earth is associated to biofilms. Biofilms and microorganisms from ► [extreme environments](#) are considered interesting astrobiological model systems (Aguilera et al. 2007b; Gómez et al. 2011; Kral et al. 2004), specially as biomarkers of extinct or extant life in habitable planets like Mars or on Galilean moons.

Biosignature

Definition

A BIOSIGNATURE IS A chemical OR morphological signatures THAT CAN BE preserved over a range of spatial scales in rocks, minerals, or ice that IS uniquely produced by past or present organisms. For example, elemental and isotopic signatures diagnostic of life that cannot be formed by purely abiotic processes. These may be accompanied by textural remains with shapes, orientations, and abundances that uniquely result from the growth, or decay of (once) living organisms. Further support for biogenicity can be shown if the distribution and abundance of this evidence are controlled by biologically significant primary variables such as light, temperature, and nutrient gradients.

Overview

Biogenicity criteria are used to assess the likelihood of a biological origin for candidate traces of life. Biogenicity criteria address observable and quantifiable features that can be broadly divided into three types: (1) the morphological complexity and size distribution of textural traces of life; (2) the elemental composition, bonding, symmetry, and isotopic composition of chemical traces of life; and (3) the environmental distribution or geological context of traces of life. These three approaches to investigating the biogenicity of candidate traces of life are mutually reinforcing and should be accompanied by efforts to falsify potential abiotic explanations for the observations. So-called ► “**dubiofossils**” or ► “**pseudofossils**” are features that are highly questionable traces of life and more likely explained by abiotic processes that can mimic life (Hofmann 1971).

Specific biogenicity criteria have been tailored for the different classes of biosignature found on earth and beyond AND HERE WE

WILL FOCUS ON EVIDENCE FOUND IN THE ROCK RECORD. For microfossils, biogenicity criteria have been proposed by SEVERAL AUTHORS, for example, Buick 1990 and Brasier et al. 2004. TO SUMMARISE THESE IN BRIEF these focus on the size distribution of the population OF CANDIDATE MICROFOS-SILS; morphological features such as branching, septation, evidence for cell walls, nuclei, or extracellular polymeric substances; their orientation especially evidence of colonial behavior, tiering, or phototaxis; and lastly evidence of primary environmentally controlled distribution and/or subsequent decay. The importance of such criteria has been highlighted by abiotic experiments that produce microfossil-like filamentous biomorphs in the laboratory, for example, (Garcia-Ruiz et al. 2003). These microfossil biogenicity criteria have also been adapted for meteorite sample, especially for those purported to contain fossilized magnetobacteria by, for example, (Thomas-Keprta et al. 2001).

For laminated sedimentary structures known as ► **stromatolites** found in carbonate rocks that form by the interaction of microbial mats and sediments, biogenicity criteria have been advanced by, for example, (Buick et al. 1981) and contrasted with abiotic artifacts by (McLoughlin et al. 2008). A primary sedimentary origin, along with complex laminated macro-morphology including domes, columns, and branches, is supportive of a biological origin for stromatolites. However, it is often the micro-fabrics of stromatolites, which preservation permitting, can be one of the best indicators of a biological origin, for example, (Hofmann 2000). For the related phenomenon of microbially induced sedimentary structures found in clastic rocks, biogenicity criteria have been formulated by (Noffke 2009). Lastly for micro-cavities produced by rock-dwelling organisms that tunnel into rock substrates, including carbonates, silicates, and volcanic glass, biogenicity criteria have been developed by, for example, (McLoughlin et al. 2007). For an up-to-date summary of biogenicity criteria please consult NASA's NfoLD (Network for Life Detection) database, which is a community effort to establish a

knowledge base to guide testing and evaluation of remote and in situ biosignatures (For an up-to-date <https://ldfknowledgebase.com/NASA> 2021).

Biogeocentrism

Octavio A. Chon-Torres

Programa de Estudios Generales, Universidad de Lima, Lima, Perú

Definition

According to Chela-Flores (2001, 2009), this term refers to the way we understand life in the universe from the only reference we have, that is, life on Earth. In this notion, biogeocentrism is shown as the current model that prevails as long as we do not have, as yet, a confirmation of other forms of life in the universe. The way we understand life on Earth represents a conditioning factor to be able to detect it in other worlds. One of the challenges we face is, what would happen if, because we are conditioned to what we understand by life and how it behaves on Earth, we are overlooking different forms of extraterrestrial life?

Definition

The biogeochemical cycles are a theoretical concept that describes the transfer of matter and energy between the biosphere and the other active reservoirs of Earth – like the atmosphere, hydrosphere, and lithosphere (Schlessinger 1997). The main processes can be understood as the biosphere's storage or release of energy by uptaking or liberating molecular species with essential components for life, the so-called nutrients. The primary biogeochemical cycles involve different molecular species whose composition provides the essential elements for building polymeric structures and obtaining energy in cells. The biogeochemical cycles are activated when the biosphere interacts with some matter fluxes that specifically supply nutrients. They are sourced from specific sites or active centers on Earth (e.g., volcanic, hydrothermal systems) that are

essentially energy sources that maintain the supply of matter and energy to the Earth's surface. As the highest-level living structure, the biosphere has its energy transducers played by autotrophic organisms. Some geological systems (e.g., hydrothermal) can also act as energy transducers to recycle oxidized compounds ultimately uptaken by chemolithotrophs, which sustain the biological communities in deep regions of the oceans (Sutton and Milligan 2019). Therefore, the energy is transported as molecular compounds from the lithosphere to the different reservoirs of the Earth (Lovelock 2000). Such geochemical processes are likely intimately related to the pre-metabolic reactions that triggered the emergence of life on Earth (Varma et al. 2018). Furthermore, they are considered essential to make a planetary body habitable as they release energy in the form of compounds and sustain the chemical disequilibrium necessary for an emerging biosphere. The Earth's inner thermal factory is a major abiotic player in the biogeochemical cycles controlled by the biosphere. The reducing power of the internal activity of Earth (Richards 2015) is obtained through the production of diverse inorganic (e.g., reduced metals) and organic compounds (e.g., methane) (Schlessinger 2020). Such compounds are uptaken by chemoautotrophic organisms as electron donors sustaining the biogeochemical cycles in different habitats. The emergence of the photoautotrophic life (Lyons et al. 2014) diversified and increased the number of pathways to cycling matter and energy between the biosphere and the other terrestrial reservoirs. While matter and energy are produced in different sources, they transfer through different Earth fluxes to end in sinks that become unavailable, depending on the physical and/or chemical process (Schlessinger and Bernhardt 2020). For example, oxidation of organics plus sequestration of CO₂ in the oceans is a temporal or permanent sink for carbon. In turn, carbon is produced from many other sources, which supply rates are enhanced by different large-scale terrestrial events. Furthermore, the dynamic of the large-scale events also may change the distribution of sources and sinks. This is the case of the large sulfide deposits that were formed under the

Archean anoxic conditions, which sequestered a large amount of the total sulfur available in the terrestrial crust. However, the release of oxygen by chemoautotrophic life to the ocean and atmosphere during the GOE (Konhauser et al. 2011) sourced sulfur and other elements to the hydrosphere through the oxidation of the terrestrial crusts by acidic alteration. In this context, during the GOE the terrestrial sulfide orebodies that were sinks for sulfide became sources of sulfur after being mobilized by the oxidation event. The biosphere's ability to transfer energy among different chemical species results in the generation of intricate pathways involving diverse element cycles. For example, it is observed in an active chemolithotrophic community associated with different hydrothermal centers that sequestered a large amount of sulfur in the form of sulfides by the high organic supply in the form of plant debris (Fernandez-Remolar et al. 2018). The supply of organic carbon was released by a catastrophic event driven by regional volcanic activity that obliterated the late Devonian forests. The chemolithotrophic communities oxidized the organic carbon to CO_2 by reducing SO_4^- found in the seawater.

Overview

The biogeochemical cycles result from a complex network of interrelated pathways that are mediated by the biosphere with the different Earth's reservoirs. In this regard, the biogeochemical cycles are the different pathways that the biosphere at any scale uses to obtain nutrients and energy to persist. Different positive and negative feedback reactions emerge from such interaction that, to some extent, can control the physical and chemical properties of the environment (Margaleff 1968). The reservoir is the fundamental unit in biogeochemistry that corresponds with a physical container of the different components that are circulated through the biogeochemical pathways after its interaction with the biosphere. As emphasized in collapse the definition, the biogeochemical cycles emerge by different matter and energy fluxes are driven by the different

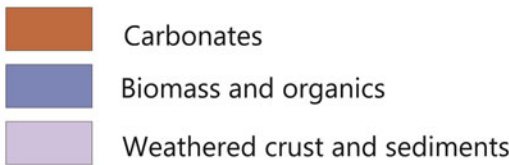

converter agents (Schlesinger and Bernhardt 2020). The converter agents are mainly the biological entities that transduce energy, transform, or store nutrients in reservoirs, which become newly available to the biosphere. Some of the active centers where the energy and nutrient converters occur have been considered to work as planetary organs to sustain the biosphere. It has been claimed that the destruction of the autotrophic centers producing oxygen would collapse the pathways sustaining the biochemical cycles and seriously compromise the biosphere itself (Lovelock 2000). However, it is uncertain if life on Earth will be fully terminated as the first living systems likely emerged from an anaerobic world. Although converters and transducers are mostly represented by living beings, there are some abiotic reactions that can initiate the biogeochemical cycles in different habitats as in the hydrothermal vents (McDermott et al. 2020) and the serpentinization systems (Schulte et al. 2008). In those habitats, the reducing power and chemical disequilibrium are obtained through the production of different reduced compounds that can provide energy to the chemosynthetic producers. Furthermore, the terrestrial reservoirs are partitioned in different lower units, which size can vary depending on the dimensions of the habitats that are associated with the biological and non-biological converter agents. While the reservoirs on earth (atmosphere, hydrosphere, biosphere, and geosphere) are partitioned in different regions matching the habitats, they also have particular parcels where the nutrients are partially removed from recycling. Significant environmental changes can, in turn, make them available, inducing large biogeochemical imbalances until a new equilibrium stage is reached. A good example is carbon release by global warming stored in deep oceans in the form of CO_2 and CH_4 , found as dissolved species or icy hydrates. A high rise of the temperature leads to a high supply of CO_2 to the atmosphere, triggering a positive feedback controlled by green housing and the production of carbonic acid. A same situation has been found in different thermal events that have been widely described to occur in different episodes of the Earth's history (Babila et al. 2018; Gehler et al.

2016; Kump 2018). In some extreme cases like during the late Permian, the atmospheric CO₂ reached a concentration of 3500 ppm (Saunders and Reichow 2009).

The biosphere stores and uses a wide range of nutrients, including those that are essential for building cellular and multicellular structures and provide energy through electron transfer or chemical bonding. Therefore, it has a large impact on the cycling of compounds (Fig. 1) that are bearing carbon, nitrogen, sulfur, or phosphorous (Brimblecombe 2014; Galloway 2014; Sundquist and Visser 2014; Ruttenberg 2014), which, in addition, were operating since the emergence of the biosphere more than 3.5 Ga ago. The nutrients can be exchanged with other reservoirs as volatiles, ions, or biominerals. As stated before, biomineral formation can eventually end in the elimination of nutrients from the biosphere through specific sites or sinks by driving them into other Earth's reservoirs.

One paradigmatic example is the limestone formation by unicellular planktonic algae and foraminifera, which biomineralize carbonate to form shells (Zondervan et al. 2001). After the microorganism's death, the carbonatic shells rain down continuously on the ocean floor, becoming the raw material leading to the global formation of sedimentary carbonates (Fig. 1). Later on, the global tectonics can transport the oceanic deposits from the sedimentary areas to the subduction zones where the carbonate is partially transformed back into CO₂ by thermal decomposition in deep areas of the lithosphere (Sundquist and Visser 2014). The CO₂ can then be returned to the atmosphere through exhalation of volatile compounds from the volcanic centers and geothermal systems. Some other nutrients like sulfide can be directly released into the atmosphere in the form of organic volatiles, which are lately transferred back to the hydrosphere and biosphere once they are oxidized by photochemical reactions. As shown by some organic compounds like dimethyl sulfide (Fig. 1), one of the main sources of sulfur in the biosphere, which is released into the atmosphere by phytoplankton, but returned to the hydrosphere in the form of sulfate after being oxidized by UV in the atmosphere (Brimblecombe 2014). The dimethyl sulfide (Fig. 1) becomes one of the primary sources

of the biosphere sulfur, released into the atmosphere by phytoplankton, but is returned to the hydrosphere in the form of sulfate after being oxidized by UV in the atmosphere (Brimblecombe 2014). Interestingly, the release of sulfur-bearing compounds into the atmosphere and their subsequent oxidation to sulfate is a crucial mechanism in nucleating clouds. It has a planetary impact on the thermal control of the Earth's temperature as it increases the albedo and, therefore, decreases the solar radiation affecting the Earth's surface (Charlson et al. 1987). Consequently, sulfur cycling by phytoplankton is an essential feedback mechanism to control climatic conditions on the planet. Other nutrients essential for life in low concentrations are released to the atmosphere following similar pathways as the iodine supplied to the atmosphere by marine phytoplankton in the form of different volatile compounds such as methyl iodide (Butler et al. 1981; Manley and de la Cuesta 1997). It is lately decomposed by photolytic reactions with oxidants in the troposphere to more oxidized forms of iodine. Finally, the iodine is returned to the lithosphere or hydrosphere by rainfall or simple influx from the atmosphere after being included in the aerosols, active cloud-nucleating agents on Earth (Baker 2005). The iodine and sulfur cycling are good examples of the emergence of feedbacks from the simple nutrient exchange between the different Earth's reservoirs that become essential homeostasis mechanisms that control the environmental conditions at a planetary scale (Charlson et al. 1987; Lovelock 2000). The homeostatic capabilities of the biosphere controlled through biogeochemical pathways are also observed at a local scale. Although it has been widely mentioned the physic and chemical control performed by different vegetal communities, some natural systems with astrobiological interest are controlled by chemical mechanisms that stabilize the environmental parameters. It is the case of the extreme hyperacidic environment of Rio Tinto, a 100-km long fluvial system that emerges from the low-pH solutions (<2.5) through the underground biooxidation of the IBP sulfide orebodies by chemolithotrophic communities. The underground microbial activity ends in the release of a solution enriched in Fe₃⁺, SO₄²⁻, and H⁺ (Fernández-Remolar et al. 2021)

- 7** Cloud nucleation by sulfuric acid generation

Biogeochemical Cycles, Fig. 1 Biogeochemical cycle of carbon coupled to the sulfur cycle. The diagram shows the main pathways and reservoirs integrating the whole carbon cycle and its interplays with the sulfur cycle. Volcanic centers and other geothermal-driven systems (e.g., hydrothermal systems) release carbon to the atmosphere (1) mainly in the form of CO_2 but also CH_4 and CO . The carbon is fixed as organic or inorganic carbon through the biosphere growth and organics (2) and the precipitation of carbonates (3), which can be produced by biomineralization, simple precipitation by biological mediation, oversaturation by abiotic mechanisms, or simple weathering. The carbon is removed from the crust by sediment burial of carbonates and organics (4); carbonate precipitations in the subsurface by biological uptake and weathering mechanisms are also effective processes to

remove carbon from the Earth's surface. The organic oxidation, thermal decomposition, or simple carbonate dissolution through diagenesis can cycle back into the atmosphere (5) the carbon as carbon dioxide to compensate the carbon loss through microbial uptake, carbonate precipitation, or simple weathering. Sulfur can be oxidized to sulfuric acid through complex photochemical reactions starting on hydrogen sulfide oxidation and ending on the sulfite hydration. Thus, sulfuric anion as a powerful nucleation agent of clouds (6) favors the supply of meteoric water to the surface that transports C-bearing gases and other volatiles to the crust, making the carbon available for its fixation as organic or inorganic compounds. Sulfur is released back to the atmosphere (7) as dimethyl sulfide supplied by algal activity

that thermodynamically favors the hydrolysis reaction through the ferric buffer ($\text{Fe}^{3+} + \text{H}_2\text{O} \rightarrow \text{Fe}(\text{OH})^{2+} + \text{H}^+$), maintaining the solution at an average pH of 2.3 for each year. Despite the extreme pH conditions, the emergence of such a homeostatic mechanism controlling the chemical conditions could be related to the high microbial diversity found in the Rio Tinto environment. Interestingly, the subsurface biooxidation of the orebody by diverse chemolithotrophic life links the nitrogen cycle with the iron and sulfur cycles. Such microorganisms obtain this nutrient as different molecular species like NH_4^+ , NO_2^+ , and NO_3^+ from the host rock which were sequestered by hydrothermalism (Fernández-Remolar et al. 2021). In this regard, the nitrogen cycle is initiated by redox coupling with the different iron and sulfur ions released from the orebody by the microbial attack. The acidic biooxidation that sustains the homeostatic conditions in the surface habitat also favors the fast release of different nutrients, including sulfur, iron, nitrogen, and phosphorous.

The last part in biochemical cycling corresponds with the transport agents, which act as natural carriers to distribute to the different Earth's reservoirs. Most of them are activated by simple physical gradients powered by local or regional changes in temperature, density, pressure, or gravity. Although potential energy plays an essential role in fluvial transport, most transporting agents are driven by the latitudinal difference in temperature. In this regard, it is worth mentioning that the hydrological cycle on Earth contributes to nutrient exchange between the different Earth's reservoirs. The interaction between the transport and the biogeochemical agents control the element fluxes that strongly affect the residence times in the different reservoirs (Schlessinger and Bernhardt 2020). The rates of the biogeochemical fluxes.

Basic Methodology

Biogeochemistry, the discipline that studies the interplay between the biosphere and the different Earth reservoirs, emerges from the interaction of

experimental sciences like physics, chemistry, biology, and geology. Thus, it uses a diverse suite of methodologies and techniques. The biogeochemical cycles are powered by matter and energy exchanges experimentally measurable by different rates, which are quantifiable in mass units per unit of time. In this sense, reaction kinetics (metabolic and chemical) and thermodynamics are essential concepts in describing how biogeochemical cycles operate (Schlessinger and Bernhardt 2020). Furthermore, system modeling is an essential tool deeply rooted in linear and nonlinear mathematics that has increased our understanding of cycling dynamics. It has also integrated the local and regional biogeochemical cycling of single nutrients with other compounds on a larger range, which provides a better comprehension of the biogeochemical processes at a planetary scale (Sellers et al. 1997). Building up system models requires the collection of accurate quantitative data to build consistent models. In this regard, spectral satellite data analysis has significantly advanced the biogeochemical process at regional or planetary scales (Frouin et al. 2018; Graham et al. 2015). However, the satellite data quantification demands a ground truth approach to calibrate it locally through sampling air, water, sediments, soils, or rocks. It can be done through different in situ analytical techniques such as spectrophotometers, visible and infrared spectroscopy, chromatography, and mass spectrometers (Viollier et al. 2003). Accurate gas analysis is frequently based on careful sampling processes that use pressurized sampling cells to collect the volatile phases. The quantification and determination of volatile fluxes in water masses, soils, or sediments are characterized by sophisticated systems that integrate the sampling cell and the instrumentation system (Heyer and Berger 2000).

Furthermore, inferring the rates of biogeochemical fluxes requires collecting samples at different time spans. It can be done from a planetary scale using successive satellite images with different collection dates to a very local scale, which can deal with the seasonal variation of nutrient concentration in a lacustrine system. Nutrients in

minerals or dissolved ions can be analyzed using various techniques that characterize their organic composition, such as atomic absorption, thermal fluorescence, and mass spectrometers. Some complex instrument suites, like ToF-SIMS and NanoSIMS, can recognize the biogeochemical processes in modern and ancient environments to characterize the distribution of organics, inorganic compounds, and isotopes in soil and rocky samples (Fernández-Remolar et al. 2018, 2021; Herrmann et al. 2007).

Key Research Findings

Some of the quintessential findings in science that life derived from Earth and are intimately integrated into the matter and energy cycles of Earth were indeed done by biogeochemistry's father Vernadsky in the early 1900s (Vernadsky 1998). Interestingly, such scientific discoveries linked prebiotic systems with particular geochemical cycles (e.g., C, S, and Fe) that have been considered as early stages of premetabolic systems (Drobner et al. 1990; Gorham 1991; Varma et al. 2018). Furthermore, chemical stoichiometry linking molecular compounds with the different terrestrial reservoirs identified the biogeochemical mechanisms to control the climatic activity and the earth's crust composition. (Garrels et al. 1975; Lovelock 1972). In this context, the study of the biogeochemical cycles in the modern earth has been essential to understand how human activity is affecting the climatic conditions on Earth (Bianchi et al. 2021). On the other hand, the characterization of the biogeochemical cycles through chemical reactions has led to the conceptual building of the different biogeochemical cycles on Earth and perform the quantitative evaluation of the element pools in natural and anthropic systems (Parton et al. 1993). The application of different techniques as the geochemistry of stable isotopes has led to the monitoring of the metabolism evolution and the biosphere composition (Nealson and Rye 2014), but also the changes in the dynamics of the biogeochemical cycles over time in close relation with the climate

and ocean evolution (Sutton et al. 2018; Sundquist and Ackerman 2014).

Applications

Given that the biogeochemistry emerges from the interaction of several disciplines, it can consequently have countless applications. For example, from environmental to agronomic sciences, biogeochemical cycles are in the central core to foresee climatic extremes or minimize the impact of crops on the environment. Regarding astrobiology, the study of the biogeochemical cycles is the core of its essential question for search life in the universe whether or not a planetary body can sustain life (Nisbet and Fowler 2014). The four main ingredients – liquid water, nutrients, energy sources, and chemical disequilibrium – that enable a planet to become potentially habitable are the same key elements that initiate and maintain the biogeochemical cycles operated by a hypothetical extraterrestrial biosphere. The chemical disequilibrium, among all ingredients, emerges as essential to fuel the matter and energy transfer that maintains the cycling. Several attempts exist to visualize how biogeochemical cycling could operate in modern planetary bodies sustained by redox disequilibrium maintained through photochemical reactions that supply oxidizing and reducing compounds to the planetary surface. For Mars, a planet covered by a thin CO₂-rich atmosphere, the radiolysis of methane has been suggested as a mechanism to provide H₂ as an electron donor for microbial life in the subsurface (Blair et al. 2007; Weiss et al. 1999). Interestingly, accurate geochemical calculations from Mars meteorites show that the deep underground oxidative processes like radiolysis affection sulfide orebodies can sustain a deep biosphere sustained by chemolithotrophs through producing H₂ and SO₄²⁻. Similar cycling for carbon is proposed for Europa (Chyba and Phillips 2001), an icy satellite of Jupiter with no atmospheric cover exposed to a heavy bombardment of ionized particles like Na⁺. Furthermore, a similar scenario to the

Mars radiolytic biosphere has also been envisaged in Jupiter's icy satellite (Altair et al. 2018).

Future Directions

It is widely discussed that biogeochemistry can play an essential role in foreseeing severe environmental issues like climate change and contamination (Bianchi et al. 2021). In this regard, it is needed to understand better the attributes of the different components in the biogeochemical cycles, particularly the biological side, which will also improve the environmental modeling (Bianchi et al. 2021). However, studying the biogeochemical cycles can not only foresee how the Earth systems will operate in the future. Such improvement will also assist in understanding the biosphere's emergence, its coevolution with Earth, and its potential emergence in other planetary bodies. As discussed above, it touches on essential questions about how the origin of life was linked to the early geochemical cycles operating in the Hadean to early Archean Earth (Keller et al. 2014). Such research also poses crucial information about the emergence of life in other planetary bodies, showing earlier evolutionary stages or following different biogeochemical pathways. The Perseverance rover is collecting a set of samples that, in the following years, might provide some clues about the geochemical cycles operating in a young terrestrial planet. Perhaps, this information will be the basis to understand how life emerged on our planet whether it did not occur on Mars or, on the other hand, reached a prebiotic stage (Clark et al. 2021). In this context, the revelation of the biogeochemical cycles involved in the emergence of life in the Solar System's terrestrial planets will also provide essential information for detecting it in some exoplanets (Seager 2014). However, the lack of knowledge of the global cycles in other terrestrial planets of the Solar System (Witze 2020) also poses questions about detecting biosignatures in exoplanets. Thus, it is a long way until we can fully understand the molecular compounds produced by the planetary geochemical cycles, which can be very unexpected as the phosphine case on

Venus or the release of methane to the Mars atmosphere (Moores et al. 2019). Such a lack of knowledge is a common issue in terrestrial planets and the geochemical cycles in icy bodies (Hörs 2017). The combination of the future exploration of the Solar System with the research of the very early geochemical systems on Earth will provide a complete picture of the critical processes linked to the emergence of the prebiotic systems that evolved to the first living forms. Such information will likely shed light on the habitability and potential emergence of prebiotic systems or biospheres in other regions in the Universe.

Definition

Bioinformatics, also called computational biology, is a recent discipline whose aims are to store, retrieve, classify, and organize information about biological systems, to detect their evolutionary and functional patterns, to suggest laws of biological organization through statistical analysis, and to predict the results of new experiments by extrapolating experimental data with

the help of evolutionary or physically inspired reasoning.

History

One can say that bioinformatics originated with the need to compare protein sequences in an objective and automatic way in the early 1960s, inspired by the recent discipline of information theory, which led to the proposal of the molecular clock in ► [protein](#) evolution. Since then, sequence analysis has become more complex, addressing the comparison of the first complete genomes in the 1990s. Anfinsen experiments in the 1950s–1970s motivated the holy grail of computational biology: to predict protein structures from physical principles (Anfinsen 1973). While this dream did not materialize yet, it attracted many physicists to the field and stimulated a very rich and fruitful dialogue with statistical mechanics. Bioinformatics is nowadays a kind of two-headed animal, trying to combine the historical approach of evolutionary theory with the universality of physical laws. This hectic field is benefiting from the open-access mentality in which scientists all over the world freely share their algorithms and databases through the Internet.

Overview

The scope of bioinformatics is rapidly evolving. Currently, its main fields are the following:

1. Sequence analysis: alignment and comparison of macromolecular sequences to predict structural and functional relationships; algorithms for fast search of related sequences in large databases, like Blast; statistical models of sequence families (hidden Markov models); and analysis of splice variants in different tissues and organisms
2. Structural bioinformatics: macromolecular structure alignment and classification; analysis of structural evolution; prediction of secondary, tertiary (protein and RNA folding), and quaternary (protein-protein and protein-nucleic acid interactions) structure; prediction of folding stability upon mutation; prediction of the protein propensity to misfold and form amyloid fibrils or amorphous aggregates, involved in diseases; analysis and prediction of conformation changes upon molecular binding; and prediction of naturally disordered regions of a protein
3. Computational drug design: virtual screening of candidate drugs by predicting their affinity to target ► [proteins](#) through protein-drug docking or other techniques
4. Analysis, classification, and prediction of protein function
5. Molecular evolution: reconstruction of evolutionary patterns and phylogenetic trees and simulations of evolutionary processes
6. Gene expression analysis: statistical analysis of mRNA levels measured through microarrays and other techniques to detect co-regulated genes and compare different cell types and tissues in health and disease
7. Proteomic analysis to detect gene expression by measuring protein content
8. Analysis and prediction of gene networks: DNA regulation through transcription factors; post-translational modifications of proteins, in particular phosphorylation; protein-protein interaction networks; and biochemical pathways
9. Algorithm improvement
10. Database management and integration
11. Last but not least, literature mining to retrieve information about biological systems of interest

Points 6–8 also belong to systems biology, an interdisciplinary field that focuses its study on the interactions between the components of biological systems, while mathematical modeling of evolutionary processes has been demonstrated to have a rigorous formal analogy with statistical physics. Bioinformatics and its sister disciplines are more and more central in a dialogue with experimental biology, both as tools for predictions and information retrieval and as a conceptual framework to look for general organizational and evolutionary principles that help us to better understand living matter.

Biological Indicator

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

In planetary protection, as well as medical sterilization procedures, biological indicators are used to establish the efficacy of a bioburden reduction process. A well-characterized preparation of microorganisms (usually spores) is subjected to the bioburden reduction or sterilization protocol and a pass/fail analysis is conducted after the protocol by attempting to grow the microorganisms from the biological indicator. Failure of growth from the biological indicator indicates success of the bioburden reduction process. A number of biological indicators are commercially available in the form of a population of spores generated from a species of microorganism with known levels of resistance to a particular bioburden reduction process.

Definition

A biological network is an abstract representation of a biological system as a graph in which nodes in the graph represent components in the system (genes, cells, molecules) and links between the nodes represent interactions between components. Links may be weighted to represent strength of interactions. The resulting graph has a particular topology which can be used to understand function.

Overview

Recent advances in technology have resulted in an explosion in the amount of data that can be collected from biological systems. Techniques such as mass spectrometry, yeast two-hybrid assays, and other high-throughput methods have enabled significant advances in the identification of components, expression patterns,

and interactions within biological systems. Analyzing such vast data sets is challenging. Furthermore, the data sets are often incomplete and perhaps inaccurate. However, by considering the biological system as a network or graph in which entities in the network are represented by nodes, with links between nodes representing interactions, the essential properties of the system can be captured in an abstracted form with definite topological structure which can be linked to functional properties of the system. This abstraction enables the applications of tools developed in fields such as complex network theory, statistical physics, and sociology to be applied to biological networks, greatly facilitating their analysis (Wuchty et al. 2003; Barabási and Oltvai 2004; Barabási and Albert 1999). It further enables the comparison of biological systems to engineered systems which are traditionally described in network form (e.g., as a flowchart) and thereby enables the identification of shared principles such as robustness, fragility, tolerance, and modularity (Alon 2003).

Many biological systems have been studied from the perspective of network theory (Zhu et al. 2007), for example:

- ► [Transcription factors](#): Data obtained from chromatin immunoprecipitation (ChIP) followed by probing of genomic microarrays and from ► [DNA sequencing](#) has been used to assemble networks describing transcription factor binding sites in yeast and mammalian cells.
- *Protein-protein interactions*: Such interactions represent the most readily available biological networks to date. Data is generated from techniques such as two-hybrid assays and other high-throughput techniques such as purification and mass spectrometry. In such networks, nodes represent proteins with edges denoting physical interactions between proteins (Jeong et al. 2001). Examples of particular protein interaction networks studied include *Saccharomyces cerevisiae* (yeast), *Helicobacter pylori*

(► [bacteria](#)), as well as those in *Drosophila* and humans.

- *Metabolic networks*: Biochemical data has enabled the construction of *metabolic networks* (e.g., ► [glycolysis](#)) which describe the metabolic and physical processes that determine the physiological and biochemical properties of cells, usually focusing on the basic chemical pathways that generate the essential components used in biochemical reactions. Nodes in such networks generally represent enzymes, with edges denoting interactions between them (Jeong et al. 2000).
- *Immune networks*: The mammalian immune system can be considered as a number of interacting networks operating at different levels separated in both time and space. Within cells, *gene networks* link genes and transcription factors controlling gene expression; intracellular signaling networks link surface receptors on cells to gene-regulatory events; other cells of the immune system such as *B-cells* and *T-cells* communicate via mediators such as cytokines and hence form cellular networks (Callard and Stark 2007).
- *Neuronal networks*: The brain consists of intricately organized networks of cortical connections; these connections can be modeled by networks in which nodes are brain regions or areas and edges represent fiber connections between them (Kepes 2007).

The examples above provide a brief insight into the diversity of biological systems that can be modeled using a network approach. Despite the obvious differences between the systems listed, the network approach provides a common framework in which these systems can be analyzed and therefore compared. Such comparisons have revealed many similarities between networks, not only those derived from biological systems but also social systems (e.g., friendship networks) and engineered systems (e.g., the World Wide Web) (Barabási and Albert 1999). This tends to indicate generic principles of organization which can be exploited to gain further understanding and will ultimately enable systems biology to combine the numerous details about molecular interactions

into a single framework, thereby offering a means to address the structure of the ► [cell](#) as a whole.

Basic Methodology

Network topology plays a key role in understanding the architecture and function of biological networks. A number of measures are commonly used to describe the structure of a biological network:

- *Degree*: The degree of a node defines the numbers of links the node has to other nodes and is the most basic measure used. The average degree $\langle k \rangle$ can be calculated; however, a more useful measure is the degree distribution $P(k)$ which describes the number of nodes in the network having k links. A Poisson-shaped degree distribution indicates that there are no highly connected nodes; in contrast, a power-law degree distribution indicates the presence of a few highly connected nodes known as *hubs*.
- *Mean shortest path*: The shortest path is a measure of the navigability of a network and describes the mean shortest distance between any two nodes in the network. Biological networks (e.g., protein interaction networks and transcriptional networks) exhibit a *small-world* property in which the mean shortest path is very small.
- *Clustering coefficient*: This measures the average probability in a network that two nodes which have a mutual parent are also connected (Watts and Strogatz 1998); using social network terminology, this can be interpreted as “the friend of your friend is likely to be your friend.” The clustering coefficient reveals important information regarding network structure. $C(k)$ measures the average clustering coefficient of nodes with k links; if $C(k)$ is independent of k , the network is either homogeneous or it is dominated by numerous small tightly linked clusters. On the other hand, if $C(k)$ follows $C(k) \sim k^{-1}$, the network has a hierarchical architecture meaning that sparsely connected nodes are part of highly clustered

regions with communication between the different regions maintained by a few hubs (Wuchty et al. 2001).

These properties can be used to classify the topology of a network into a number of *models*. Biological networks tend to be *scale free* in that they are characterized by a degree distribution which follows a *power law* $P(k) \sim k^{-\gamma}$, i.e., most nodes in the network participate in very few interactions, but a small number participate in many and therefore function as *hubs*. Many biological systems are intrinsically *modular*, i.e., functionality is achieved via a set of physically or functionally linked modules which work together. Modularity is accounted for in *hierarchical network models* which assume that clusters can combine together in an iterative manner to generate a hierarchical or layered structure (Barabási and Oltvai 2004).

Key Research Findings

The application of network analysis techniques to biological systems, made possible by the abstraction of biological systems as networks, indicates:

- Power-law degree distributions emerge as a universal law characterizing cellular networks (Barabási and Albert 1999).
- Many biological networks have the same topological scaling properties as complex non-biological systems such as social networks or the World Wide Web, despite obvious differences in their components and structure, and furthermore show striking similarities to the inherent organization of nonbiological systems (Barabási and Albert 1999).
- Integrity and robustness of biological networks are facilitated by structures which contain a few highly connected hubs, e.g., genes which can integrate multiple signals or trigger widespread attacks (Wuchty et al. 2003; Jeong et al. 2001); this ensures robustness against random failures but at the same time makes them vulnerable to targeted attacks. This is consistent with experimental data suggesting that most mutations have little phenotypic effect but that networks are extremely vulnerable to attack at certain critical genes.
- The observed modularity found in biological networks via network analysis supports the notion that evolution acts over multiple levels (Wuchty et al. 2003); organisms can increase in complexity via copying and reuse of existing modules over time; furthermore, modules can be readily reconfigured to adapt to new conditions through evolution (Gerhart and Kirschner 1997).
- Many different biological systems contain common *motifs* – subgraphs of a network which are overrepresented when compared to a randomized version of the same network. For example, triangular motifs which have feed-forward functionality are found in both transcription-regulatory and feed-forward networks. Data obtained from yeast transcription networks points to the evolutionary conservation of key motif patterns with distinct functionalities.

Applications

Understanding the underlying structure of biological networks may eventually enable a complete description of the biological networks of a complete cell to be elucidated, promising great benefits to medicine in the future. The identification of hubs – the highly connected nodes in a network – leads to the possibility of being able to identify potential targets for drug design. The ability to target the high-degree proteins in a network could lead, for example, to new strategies for therapeutic mediation of signaling pathways in cancer. Interactions in metabolic networks are closely related to the ► *gene* functions and therefore have great potential for immediate applications in the interpretation of gene roles. Identification of unknown pathogenic genes might help shed light on disease pathogenic mechanisms (Zhu et al. 2007). Advancement in our understanding of cytokine connectivity architectures has already demonstrated that immune cells do not function merely as individual clones but work in innately integrated and hierarchical collectives, shedding new light on immune-body systems organization and our

understanding of the role of the immune system in wound healing and angiogenesis (Frankenstein et al. 2006). Manipulating the cytokine network has led to novel approaches in treating acute and chronic diseases, including cancer (Vilcek and Feldmann 2004).

Future Directions

Advancements in technology will increasingly extend our abilities to accurately collect vast quantities of data. This will be coupled with advancements in theoretical tools and methods which will continue to drive forward understanding of the complex interactions occurring *within* cells, extending our understanding to intercellular networks and eventually extending it to cellular networks of complete organisms.

The science of complex networks has already played a significant role in increasing understanding of the *structural* aspects of biological networks. Future research will additionally need to take account of the *dynamic* aspects of cellular networks, including temporal and spatial aspects of activity and interactions within biological networks. Development of a novel framework in which the function of biological networks can be interpreted heralds a new era of understanding of biology, disease pathologies, and medicine in the future.

Biological Safety Level

Catharine A. Conley
NASA Headquarters, Washington, DC, USA

Synonyms

[BSL](#)

Definition

The biological safety level (BSL) is used in the USA to describe a set of specifications for the precautions required to isolate potentially hazardous biological agents in a containment facility at a specified stringency, ranging from BSL-1, which indicates the least strict containment, to BSL-4, which is the containment required for the most hazardous human pathogens. A similar scale is used in the European Union using the abbreviation P1-P4, where P indicates either pathogen or protection. For instance, a BSL-4 laboratory (P4 in Europe) is under reduced pressure relative to atmospheric pressure, the exhaust air is filtered, and all wastes including water and any hardware leaving the high-containment area are sterilized chemically or by heating. Trained personnel work inside the area in protective suits, overpressurized by air pumped in from outside through a dedicated system. The exterior of the suit is chemically disinfected when workers leave the area.

Definition

Biomarkers, biosignatures, and traces of life are three different terms or expressions related to the search for life in the Earth's rock record or beyond the Earth. However, they have different meanings, depending on the field of research where they are used or depending on the “philosophy” of the user.

Overview

Biomarkers or “markers of life” or “traces of life” include chemical, morphological, sedimentary, or isotopic processes or structures that are biogenic and could be detected to infer the past or present presence of life.

However, in practice, astrophysicists use “biomarkers” for gases of possible biological origin that could be detected in a planetary atmosphere. Geochemists use “biomarkers” for ► [molecular fossils](#) (fossil molecules such as steranes and hopanes). Paleontologists use “biomarkers” for morphological and biosedimentary fossils. Some scientists would use “biomarkers” for all possible traces of life. The term “biosignatures” is very common in the literature as a general term for all possible traces of life. However, astrobiologists now realize that discriminating possible traces of life from unambiguous traces of life is extremely difficult in the early Earth rock record and even more challenging in an extraterrestrial context. Detecting life requires a set of multidisciplinary approaches and criteria and a large (and always improving but never completed) understanding of natural processes. Therefore, rather than using the term “signatures” or “biosignatures,” the expression

“traces of life” or even better “indices of life” or “bioindices” should be favored.

Bioindicators

Definition

In exoplanet science the term “biomarker” or “bioindicator” refers to an indication (or “hint”) that life as we know it could be present – but in order to decide more definitively, additional information would be required.

Overview

The detection, e.g., of atmospheric methane in an exoplanetary atmosphere would constitute a biomarker because additional information is needed in order to determine whether or not the source is biological. This, in the case of methane, can be tested, e.g., by comparing the ratio of its outgassing amount with other outgassed species such as H₂ (see, e.g., Oze et al. 2012) and/or by determining the carbon isotope ratio (as discussed in the review of Etiope and Sherwood Lollar 2013). In contrast, the term “biosignature” refers to a robust signal that is strongly suggestive of life. For example, the atmospheric detection of an Earth-like amount of nitrous oxide (N₂O) for an Earth-like planet orbiting a sun-like star would constitute a biosignature because according to current knowledge, such a signal could not be produced by anything other than microbes. In other words, the known atmospheric abiotic sources (for an overview see, e.g., Kaiser and Röckmann 2005) for this gas are much too slow to “mimic” life in such a case.

The boundary between a biomarker and a biosignature is not strictly defined. Strong (technological) biosignatures indicative of advanced life have been suggested, e.g., the detection of emitted electromagnetic waves similar to those on Earth or the atmospheric detection of (industrially produced) chlorofluorocarbons. In such cases, it is unforeseeable as to how these signals could arise without (intelligent) life.

The detection of O₂ (hence O₃ from which it is formed) would immediately initiate a debate as to the origin – biotic or otherwise – of such signals. Any process which produces significant

atomic oxygen (O), e.g., via CO₂ photolysis (potentially important in thick, Venus-like atmospheres) and/or H₂O photolysis (potentially important in hot, steam atmospheres), can, via the self-reaction of O, lead to abiotic O₂ production in the atmosphere. Selsis et al. (2002) discuss these issues. To address the question whether *Earth-like amounts* of atmospheric O₂ and O₃ could constitute a biosignature, would therefore benefit from more theoretical studies to improve understanding of the associated range of abiotic sources.

Vegetation on Earth produces simple organic molecules such as chloromethane (CH₃Cl) (Hewitt and Jackson 2009), but again each case in hand would need to be investigated by applying theoretical studies adapted to the particular conditions (e.g., stellar flux, spectrum, etc.) in order to determine the (in situ abiotic) gas-phase sources. In this process of elimination, life is the “last man standing.”

Biomarkers Atmospheric, Evolution over Geological Time

Lisa Kaltenegger

Cornell University, Ithaca, NY, USA

Definition

The spectrum of the Earth has not been static throughout the past 4.6 billion years. This is due to the temporal variations in atmospheric molecular abundances and temperature structure and in the surface morphology and ► [albedo](#). Observations of Earth-like planets at different geological ages will certainly help us understand the diversity and some common features of terrestrial planets, including ours. For our own planet, models show varying biomarkers over geological times that could be detected in the spectrum (see, e.g., Schindler and Kasting 2000; Pavlov et al. 2000; Traub and Jucks 2006; Kaltenegger et al. 2007) to characterize it in terms of habitability and the possible presence of life.

[Biosignature](#); [Trace of life](#)

Definition

Morphological biosignatures comprise objects or structures of biological origin. They include body fossils, biominerals, and microbially influenced sedimentary structures preserved in carbonates (such as ► [stromatolites](#)), in siliciclastics (such as MISS), or other rock types.

Overview

Body fossils include microfossils and macrofossils of various compositions and modes of fossilization. Microbially influenced sedimentary structures include stromatolites (laminated carbonate rocks precipitated or trapped by microorganisms), thrombolites (unlaminated carbonate rocks precipitated or trapped by microorganisms), oncolites (small carbonate spheres with concentric laminations precipitated by

microorganisms), and MISS (a range of sedimentary structures produced by the presence and activity of ► [microbial mats](#) in siliciclastic sediments). Biominerals can be passively produced or actively produced by the organisms, and the frontier between a biological or abiological origin is tenuous. Ichnofossils or fossil traces of activities such as burrows, trails, and tracks are sometimes considered as morphological biomarkers. Abiotic processes can produce structures resembling microfossils (► [Pseudofossil](#)). Chemical precipitates can look like stromatolites. Minerals can self-assemble into complex structures that resemble body fossils or biominerals. Deciphering the ► [biogenicity](#) of an object or a structure is thus very difficult even using cutting-edge in situ techniques. Several criteria have been proposed in the literature in order to test their biogenicity. Most of them underline the importance of proving the endogenicity, the syngeneity, and the biogenicity of the structures in question in a well-characterized geological context. An additional falsification approach is required to exclude all possible abiotic hypotheses before a biological origin can be accepted.

Basic Methodology

Geobiological investigations in recent and past environments have determined the criteria for biogenicity of macroscopic and microscopic morphological signatures of life.

Laboratory studies including artificial cell degradation, bioalteration of minerals, and mineralization experiments might reveal biotic patterns and preservable properties, although these studies may not reflect the full complexity of natural environmental conditions. Documentation of abiotic patterns and morphologies is also essential, but is difficult outside the lab on our biological planet.

When trying to understand the origin of a possible morphological biomarker, three main aspects need to be considered: (1) The preservational environments: what conditions preserve cells with varying biochemical properties?

(2) The taphonomy: how do processes of degradation and preservation retain, alter, or erase original biological properties? (3) The criteria for biogenicity: how can we tell biological from nonbiological?

Key Research Findings and Applications

Body Fossils

A body fossil is any morphological remain of an organism after its death. It can have various sizes (microscopic to macroscopic) and composition (organic or mineral) and may represent a whole organism, part of an organism, or colonial organisms. Body fossils can have a variety of morphologies and chemical composition, depending on their original properties and the conditions in which they are preserved. The organic composition may be transformed to various extents or erased by the complex processes of fossilization. The mineral composition may be primary (produced or precipitated by the organism) or secondary (the original carbonaceous or mineral walls or envelopes being in that case partially or completely replaced by other minerals). Body fossils may also be preserved as molds. In that case, the fossils are first dissolved then the hole in shape of the fossil is filled with a secondary mineral.

It is difficult to prove the biogenicity of microscopic body fossils in absence of carbonaceous material. Microscopic cellular casts and molds formed by various minerals can preserve or obscure the presence of a sheath and/or significantly alter the size of the microbes. For example, bacterial cells preserved by silicification (replaced by silica) are difficult to discriminate from chemical precipitates. The organic composition of a structure does not prove its biogenicity. The term “organic” just indicates the presence of molecules with carbon and hydrogen. Organic matter is common in the universe and occurs in interstellar medium and in meteorites or is produced abiotically by chemical reactions in hydrothermal conditions on Earth. Therefore, more criteria are required to assert the biogenicity of carbonaceous material.

Microscopic and microchemical analyses of fossils isolated from shales or embedded in various rocks are needed to demonstrate a range of preservable biological properties, as well as to determine the taphonomic processes specific to the preservational environment and to the original biology. The microfossils can be characterized by their preserved walls (structure and ultrastructure) or sheaths, pigment and biopolymer composition, morphology (regular cellular shape, complex shape, ornamentation, structured organic matter), abundance (population) and distribution in the rock, orientation recording behavior and motility of benthic organisms (e.g., mats with vertical filaments erected toward light), or passive sedimentation of planktonic cells, pattern of cellular division, and, very importantly, their taphonomy (producing features such as collapsed folded flexible hollow vesicles, sinuous segmented filamentous shape, and pigmented surfaces of colonies).

Biominerals

Biominerals are minerals formed by organisms. Biominerals can be passively produced or actively produced by the organisms, and the frontier between a biological or abiological origin is ambiguous. Biologically induced mineralization (BIM) includes biominerals formed through the metabolic activity of microorganisms. Biologically controlled mineralization (BCM) includes biominerals whose formation is genetically controlled by microorganisms. Associations of biological tissues with minerals like bones or macroscopic and microscopic shells or plates are easy to consider as body fossils and are examples of BCM. Microscopic mineral precipitates onto cells or sheaths or coated streamers or filament bundles are more difficult to interpret in absence of the cell or filament and can be BIM or BCM. These precipitates may or may not form in absence of the microorganisms. The controversy regarding the magnetite minerals found in the Martian meteorite ALH84001 is a good illustration of the problem. Observations in natural settings and experiments in the laboratory can help determine criteria for biogenicity.

Microbially Induced Sedimentary Structures (MISS) and Stromatolites

These structures are produced by the interaction between a microbial mat and the surrounding sedimentary environment. They can be preserved in carbonates or in siliciclastics. They include a variety of laminated or unlaminated precipitates and/or trapped and bound mineral grains. ► [Stromatolites](#) are found in the rock record since the early Archean. They reach large sizes around 2.7 Ga when their biogenicity is not questioned. Criteria such as rock fabrics, presence and distribution of carbonaceous material or cells or filaments, unevenness of laminae, angle of repose of laminae, etc., are investigated to prove or disprove the biogenicity of these carbonate structures.

The process controlling the genesis of stromatolites is not yet well understood, although the association of macroscopic morphology with water energy is clear. Other structures indicating the presence of microbial mat interacting with the sediment include particular fabric in sandstone, pinnacles, and other irregular mat surface morphologies. Again, observations in natural settings and experiments in the laboratory can help determine criteria of biogenicity. The presence of body fossils strengthens the biogenicity of the ► [microbially induced sedimentary structures](#).

Future Directions

Defining morphological (and other) biosignatures is not a simple task. The taphonomic processes differ depending on the preservational environments and the original biology, leading to bias in fossil diversity and morphology, often preventing identification or even recognition. A better understanding of these environments and their particular fossilization processes will help to make predictions of the types of biosignatures to search for in possible past or present extraterrestrial habitats (where and what to look for), important when deciding landing sites and instrumentation for exobiological missions in situ and for returned

samples. Characterizing the taphonomic processes and the criteria for recognition of biogenicity will help interpret future observations in early Earth and extraterrestrial records.

However, the early Archean record of stromatolites and of microscopic biosignatures is still actively debated, illustrating the difficulty (or impossibility) of defining unambiguous traces of life in very old rocks, much less on another planet where knowledge of the geological background is limited. Therefore, when searching for traces of life in ancient and extraterrestrial materials, a multitude of complementary studies and biomarkers or bio-indices (not only morphological biomarkers) should be used. All possible abiotic explanations should be considered and discarded before reaching an acceptable level of reliability in any interpretation of biogenicity. Nevertheless, the conclusions will always be limited by our current understanding of the natural processes involved.

and characterize a planetary environment. Here we concentrate on characterizing a habitable planet using spectroscopy and discuss which features could point toward a biological origin (see also ► [Habitable planet, characterization](#); [Habitability, effects of eccentricity](#); ► [Habitability, effects of stellar irradiation](#); ► [Habitability of the solar system](#)).

History

Sagan et al. (1993) analyzed a spectrum of the Earth taken by the Galileo probe, searching for signatures of life, and concluded that the large amount of O₂ and the simultaneous presence of traces of CH₄ are strongly suggestive of biology. After a decade rich in giant exoplanet detections, observational techniques have now reached the ability to find planets of less than 10 M_{Earth} (so-called ► [Super-Earths](#)) that may potentially be habitable.

Overview

We discuss how we can read a planet's spectrum to assess its habitability and search for the spectral signatures of a biosphere. To characterize a planet's atmosphere and its potential habitability, we look for absorption features in the reflection and transmission spectrum of the planet. On Earth, some atmospheric species exhibiting noticeable spectral features in the planet's spectrum result directly or indirectly from biological activity: The main ones are O₂, O₃, CH₄, and N₂O. CO₂ and H₂O are in addition important as greenhouse gases in a planet's atmosphere and potential sources for high O₂ concentration from photosynthesis. Future remote-sensing characterization of planetary environments can be used to test our understanding of the factors that contribute to planetary habitability. To detect such features remotely with first-generation spectroscopy mission that will not resolve the planet, the atmosphere has to show such chemical features globally.

Keywords

Biomarkers · Extrasolar planets · Habitability · Habitable zone · Planetary atmospheres · Spectroscopy

Definition

The spectrum of a planet can contain signatures of atmospheric species that can remotely indicate habitable conditions. Some of the chemical species can indicate habitable conditions and some (combinations) can indicate biota on a planet. It is their presence and abundance along with other atmospheric species, in a certain context (e.g., the properties of the star and the planet), that can explore the underlying physics

Introduction

Dedicated future space missions will have the explicit purpose of detecting other Earth-like worlds, analyzing their characteristics, determining the composition of their atmospheres, investigating their capability to sustain life as we know it, and searching for signs of life. This can set our own planet, the only known habitat, in context with other rocky worlds and expand our statistics of 3 for rocky planets that could potentially support life. Searches will concentrate on planets in the so-called ► [habitable zone](#) (HZ) where water could remain liquid if present and gases produced by biota could easily exchange with and influence the atmosphere. The HZ is defined for surface conditions only.

Our search for signs of life is based on the assumption that extraterrestrial life shares fundamental characteristics with life on Earth, in that it requires liquid water as a solvent and has a carbon-based chemistry (see, e.g., Brack 1993; Des Marais et al. 2002). Life on the basis of a different chemistry is not considered here, because the vast range of conceivably possible life-forms might produce signatures in their atmosphere that are so far unknown. Therefore, we assume that extraterrestrial life is similar to life on Earth in its use of the same input and output gases and that it exists out of thermodynamic equilibrium (Lovelock 1975). “Biomarkers” here refer to detectable species or a set of species, whose presence at significant abundance strongly suggests a biological origin (e.g., couple $\text{CH}_4 + \text{O}_2$ or $\text{CH}_4 + \text{O}_3$ (Lovelock 1975)). A bioindicator is maybe indicative of biological processes but can also be produced abiotically.

Chemoautotrophic life, whose metabolism does not depend on the stellar light, can still exist outside the HZ, thriving in the interior of the planet where liquid water is available. Such metabolisms (see Extremophile) rely on very limited sources of energy (compared to stellar light) and electron donors (compared to H_2O on Earth). They mainly catalyze reactions that would occur at a slower rate in purely abiotic conditions, and they are thus not expected to modify a whole planetary environment in a way detectable remotely.

Basic Methodology

Atmospheric Features of a Habitable Planet

A planet observed remotely is a very faint, small object close to a very bright and large object, its parent star. The Earth is about a million times fainter than the Sun in the mid-infrared and about a billion times fainter than the Sun in the visible. Suppressing the starlight to that degree allows collecting the planet’s light and characterizing its atmosphere.

Key Research Findings

Spectra of Earth in Reflection, Emission, and Transmission

Figure 1 shows observations and model fits to the spectra of the Earth in three wavelength ranges, the visible and near infrared represent the reflected starlight, while the infrared (IR) spectrum is generated by the emitted heat flux of the planet (Kaltenegger et al. 2007). For the data shown in Fig. 1 (a) is the visible earthshine spectrum (Woollf et al. 2002), (b) is the near-infrared earthshine (defined as light from the Sun reflected from the Earth to the Moon and back again) spectrum (Turnbull et al. 2006), and (c) is the thermal infrared spectrum of the Earth as measured by a spectrometer en route to Mars (Christensen and Pearl 1997). The data are shown in black and the Smithsonian Astrophysical Observatory model in red. In each case, the constituent gas spectra in a clear atmosphere are shown below, illustrating how each molecule contributes to the overall spectrum.

Figure 2a shows observations (Iriarte 2002) and model fits to transmission spectra of the Earth (Kaltenegger and Traub 2009) that represent the transit of the Earth. The data are shown in blue and the model in red. A transmission spectrum gives the apparent radius of a planet versus wavelength. Different molecules in the planet’s atmosphere absorb part of the stellar light and make the planet appear bigger than its solid radius at characteristic wavelengths, depending on the molecule. This is shown here as effective height in the atmosphere. The

Biomarkers, Spectral, Fig. 1 Observed reflectivity spectrum in the visible (Woolf et al. 2002) (a) and near infrared (Turnbull et al. 2006) (b) and emission spectrum in the infrared (IR) (Christensen and Pearl 1997) (c) of the

integrated Earth, as determined from earthshine and space, respectively. The data are shown in black and the Smithsonian Astrophysical Observatory model in red. The reflectivity scale is arbitrary

atmospheric features are indicated. For details on the Earth's transmission spectrum during a lunar eclipse, see Palle et al. (2009) and Vidal-Madjar et al. (2010).

Both spectral regions contain the signature of atmospheric gases that may indicate habitable conditions and, possibly, the presence of a biosphere: CO_2 , H_2O , O_3 , CH_4 , and N_2O in the

thermal infrared and H_2O , O_3 , O_2 , CH_4 , and CO_2 in the visible to near infrared in reflection (Fig. 1) and transmission spectra (Fig. 2). The presence or absence of these spectral features (detected individually or collectively) will indicate similarities or differences among the atmospheres of terrestrial planets and their astrobiological potential.

Biomarkers, Spectral,

Fig. 2 Synthetic transmission spectra of the Earth from UV to IR (Kaltenegger and Traub 2009) for a cloudless atmosphere based on shuttle data (Irione 2002) and calculated for a line of sight at the tangent height indicated on the right (a). A transmission spectrum gives the apparent radius of a planet versus wavelength. Different molecules in the planet's atmosphere absorb the stellar light and make the planet appear bigger than its solid radius at characteristic wavelengths, depending on the molecule. This is shown here as effective height in the atmosphere (b). The atmospheric features are indicated below

**Characterizing Planetary Environments**

It is relatively straightforward to remotely ascertain that the Earth is a habitable planet, replete

with oceans, a greenhouse atmosphere, global geochemical cycles, and life – if one has data with arbitrarily high signal-to-noise ratio and

spatial and spectral resolutions. The interpretation of observations of other planets with limited signal-to-noise ratio and spectral resolution, as well as absolutely no spatial resolution, as envisioned for the first-generation instruments, will be far more challenging. This implies that we need to gather information on the planet's environment to understand what we will see. We can then test if we have an abiotic explanation of all compounds seen in the atmosphere of such a planet. If we do not, we can work with the exciting biotic hypothesis.

O₂ and O₃ in combination with a reducing gas like CH₄ are good biomarker candidates. Reduced gases and oxygen have to be produced concurrently to be detectable in the atmosphere, as they react rapidly with each other. Thus, the chemical imbalance traced by the simultaneous signature of O₂ and/or O₃ and of a reduced gas like CH₄ can be considered as a signature of biological activity (Lovelock 1975). These species can be detected by a low-resolution spectrograph (O₂ in the visible with a resolution <100, O₃ and CH₄ in the infrared with a resolution <50). Note that if the presence of biogenic gases such as O₂/O₃ + CH₄ may imply the presence of a massive and active biosphere, their absence does not imply the absence of life. Life existed on Earth before the interplay between oxygenic photosynthesis and carbon cycling produced an oxygen-rich atmosphere.

Temperature and Radius of a Planet

Knowing the temperature and planetary radius is crucial for a general understanding of the physical and chemical processes occurring on the planet (e.g., tectonism, atmosphere, escape). In theory, spectroscopy can provide some detailed information on the thermal profile of a planetary atmosphere (see atmospheric structure). This, however, requires a spectral resolution and a sensitivity that are well beyond the performance of a first-generation spacecraft. Generally, the surface temperature of a planet at a specific distance from its star depends on its ► [albedo](#) and on the greenhouse warming by atmospheric compounds. However, even with a low-resolution spectrum of the thermal emission, the mean effective temperature can be obtained from the peak of the

blackbody curve in the infrared (IR). The measured IR flux can directly be converted into a brightness temperature that will provide information on the temperature of the atmospheric layers responsible for the emission. The overall flux of the planet in the IR is determined by the surface area of the planet and its effective temperature; therefore, the radius of the emitting surface (e.g., ground or cloud layers; see ► [Clouds](#)) of the planet can be obtained.

The ability to associate the spectrum with a surface temperature relies on the existence and identification of spectral windows probing the surface or specific atmospheric levels. Such identification is not trivial. For an Earth-like planet, there are some atmospheric windows that can be used in most of the cases, especially between 8 and 11 µm. This window would, however, become opaque at high H₂O partial pressure (e.g., in the inner part of the habitable zone (HZ) where a lot of water is vaporized) and at high CO₂ pressure (e.g., a very young Earth or the outer part of the HZ). The accuracy of the radius and temperature determination will depend on the quality of the fit (and thus on the sensitivity and resolution of the spectrum), the precision of the Sun-star distance, the cloud coverage, and also the distribution of brightness temperatures over the planetary surface. Assuming the effective temperature of our planet were radiated from the uppermost cloud deck at about 12 km would introduce about 2% error on the Earth's radius derived from emergent and/or transmission spectra. For transiting planets, the accuracy of the radius of the planet depends on how well the host star is characterized.

Potential Biomarkers

Owen (1980) suggested searching for O₂ as a tracer of life. Oxygen in high abundance is a promising bioindicator. Oxygenic photosynthesis, the by-product of which is molecular oxygen extracted from water, allows terrestrial plants and photosynthetic bacteria (cyanobacteria) to use abundant H₂O, instead of having to rely on scarce supplies of electron donors like H₂ and H₂S to reduce CO₂. With oxygenic photosynthesis, the production of the biomass becomes limited only by nutrients and no longer by energy (light in this

case) nor by the abundance of electron donors. Oxygenic photosynthesis at a planetary scale results in the storage of large amounts of radiative energy in chemical energy, in the form of organic matter. For this reason, oxygenic photosynthesis had a tremendous impact on biogeochemical cycles on Earth and eventually resulted in the global transformation of the Earth's environment. Less than 1 ppm of atmospheric O_2 comes from abiotic processes (Walker 1977). Cyanobacteria and plants are responsible for the biotic production by using solar photons to extract hydrogen from water and using it to produce organic molecules from CO_2 . This metabolism is called oxygenic photosynthesis. The reverse reaction, using O_2 to oxidize the organics produced by photosynthesis, can occur abiotically when organics are exposed to free oxygen or biotically by both eukaryotes and certain prokaryotes using O_2 and consuming organics.

Due to a balance in the above processes, the net release of O_2 in the atmosphere actually depends on the burial of organics in sediments. Each reduced carbon buried results in a free O_2 molecule in the atmosphere. This net release rate is also counterbalanced by the weathering of fossilized carbon when exposed to the surface. The oxidation of reduced volcanic gases such as H_2 and H_2S also accounts for a significant fraction of the oxygen losses. The atmospheric oxygen is recycled through respiration and photosynthesis in less than 10,000 years. In the case of a total extinction of the Earth's biosphere, the atmospheric O_2 would disappear in a few million years.

The spectrum of the Earth has exhibited a strong infrared signature of ozone for more than 2 billion years and a strong visible signature of O_2 for an undetermined period of time between 2 and 0.8 billion years (depending on the required depth of the band for detection and also the actual evolution of the O_2 level; Kaltenegger et al. 2007). This difference is due to the fact that a saturated ozone band appears already at very low levels of O_2 (10^{-4} ppm), while the oxygen line remains unsaturated at values below the present atmospheric level (Segura et al. 2003). The depth of the saturated O_3 band is determined by the temperature difference between the surface-to-clouds

region (producing the spectral continuum) and the ozone layer.

N_2O is produced in abundance by microbial life but only in negligible amounts by abiotic processes. Nearly all of Earth's N_2O is produced by the activities of anaerobic nitrifying and denitrifying bacteria. N_2O would nevertheless be hard to detect in the Earth's atmosphere with low resolution, as its abundance is low at the surface (0.3 ppmv) and falls off rapidly in the stratosphere. Spectral features of N_2O would become more apparent in atmospheres with more N_2O and/or less H_2O vapor. Segura et al. (2003) have calculated the level of N_2O for different O_2 levels and found that its abundance decreases together with O_2 .

The methane found in the present atmosphere of the Earth has a biological origin, except for a small fraction produced abiotically in hydrothermal systems where hydrogen is released by the oxidation of ferrous iron by H_2O and reacts with CO_2 . Depending on the degree of oxidation of a planet's crust and upper mantle, such non-biological mechanisms can produce large amounts of CH_4 under certain circumstances. Therefore, the detection of methane alone cannot be considered a sign of life, while its detection in an oxygen-rich atmosphere would be difficult to explain in the absence of a biosphere. Note that methane on Mars has been suggested (Mumma et al. 2009), while the atmosphere of Mars contains 0.1% of O_2 and some ozone. In this case, the amounts involved are extremely low, and the origin of the Martian O_2 and O_3 is known to be photochemical reactions initiated by the photolysis of CO_2 and water vapor. If confirmed, the presence of methane could be explained by subsurface geochemical process, assuming that reducing conditions exist on Mars below the highly oxidized surface. The case of NH_3 is similar to the one of CH_4 . They are both released into the Earth's atmosphere by the biosphere with broadly similar rates, but the atmospheric abundance of NH_3 is orders of magnitude lower due to its very short lifetime under UV irradiation. The detection of NH_3 in the atmosphere of a habitable planet would thus be extremely interesting, especially if found with oxidized species. The detection of H_2O and CO_2 are important in the search

for signs of life not as biosignatures themselves but because they are raw materials for life and thus necessary for planetary habitability.

There are other molecules that could, under some circumstances, act as excellent biomarkers; for example, the manufactured chlorofluorocarbons (CCl_2F_2 and CCl_3F) are observed in our current atmosphere in the thermal infrared wave band, but their abundances are currently too low to be spectroscopically observed at low resolution.

Applications

Low-Resolution Spectral Information in the Visible to Near IR

In the visible to near infrared, one can see increasingly strong telluric H_2O bands at 0.73, 0.82, 0.95, and 1.14 μm . The strongest O_2 feature is the saturated Fraunhofer A-band at 0.76 μm . A weaker feature at 0.69 μm cannot be seen with low resolution. O_3 has a broad feature, the Chappuis band, which appears as a broad triangular dip in the middle of the visible spectrum from about 0.45 to 0.74 μm . The feature is very broad and shallow. Methane at present terrestrial abundance (1.65 ppm) has no significant visible absorption features, but at high abundance it has strong visible bands at 0.88 and 1.04 μm , readily detectable, for example, in early Earth models. CO_2 has negligible visible features at present Earth abundance, but in a high CO_2 atmosphere of 10% CO_2 , like in an early Earth evolution stage, the weak 1.06- μm band could be observed. In the UV, O_3 shows a strong feature that is not discussed here. The red edge of land plants due to chlorophyll developed about 0.44 Ga. It could be observed on a cloudless Earth or if the cloud pattern is known.

Low-Resolution Spectral Information in the Mid-IR

In the mid-IR for Earth, the detectable signatures of biological activity in low resolution are the combined detection of the 9.6- μm O_3 band, the 15- μm CO_2 band, and the 6.3- μm H_2O band or its rotational band that extends from 12 μm out into the microwave region (Selsis 2003). The 9.6- μm O_3 band is highly saturated and is thus a poor

quantitative indicator but an excellent qualitative indicator for the existence of even traces of O_2 . CH_4 is not readily identified using low-resolution spectroscopy for present-day Earth, but the methane feature at 7.66 μm in the IR is easily detectable at higher abundances (e.g., 100 $\times$ on early Earth; Kaltenegger et al. 2007), provided that the spectrum contains the whole band and a high enough signal-to-noise ratio. Taken together with molecular oxygen, abundant CH_4 can indicate biological processes (see also Sagan et al. 1993; Segura et al. 2003). Although methane's abundance is less than 2 ppm in the Earth's atmosphere, the 7.75- μm band shows up in a medium-resolution ($\text{Res} = 100$) infrared spectrum. Three N_2O features in the thermal infrared are detectable at 7.75 and 8.52 μm and at 16.89 μm for levels higher than in the present atmosphere of the Earth.

Abiotic Sources of Biomarkers

Abiotic sources of biomarkers are very important to assess, so that we can identify when they might constitute a ► “false positive” for life. CH_4 is an abundant constituent of the cold planetary atmospheres in the outer solar system. On Earth, it is produced abiotically in hydrothermal systems where H_2 (produced from the oxidation of Fe by water) reacts with CO_2 in a certain range of pressures and temperatures. In the absence of atmospheric oxygen, abiotic methane could build up to detectable levels. Therefore, the detection of CH_4 cannot be attributed unambiguously to life.

O_2 also has abiotic sources, e.g., (a) the photolysis of CO_2 , followed by recombination of O atoms to form O_2 ($\text{O} + \text{O} + \text{M} \rightarrow \text{O}_2 + \text{M}$), and (b) the photolysis of H_2O followed by escape of hydrogen to space. The first source results in a steady state maintained by photodissociation by the stellar UV radiation but with a constant elemental composition of the atmosphere, while the second one is a net source of oxygen. In order to reach detectable levels of O_2 (in the reflected spectrum), the photolysis of CO_2 has to occur in the absence of outgassing of reduced species and in the absence of liquid water, because of the wet deposition of oxidized species. Normally, the detection of the water vapor bands simultaneously with the O_2 band can rule out this abiotic mechanism (Segura

et al. 2007), although one should be careful, as the vapor pressure of H₂O over a high-albedo icy surface might be high enough to produce detectable H₂O bands. In the infrared, this process cannot produce a detectable O₃ feature (Selsis et al. 2002). The loss of hydrogen to space can result in massive oxygen leftovers: More than 200 bars of oxygen could build up after the loss of the hydrogen contained in the Earth's oceans. However, the case of Venus tells us that such oxygen leftover has a limited lifetime in the atmosphere (because of the oxidation of the crust and the loss of oxygen to space): We do not find O₂ in the Venusian atmosphere despite the massive loss of water probably experienced in the early history of the planet. Also, such evaporation-induced buildup of O₂ should occur only closer to a certain distance from the star and affect small planets with low gravity more dramatically than more massive planets. For small planets ($<0.5 M_{\text{Earth}}$) close to the inner edge of the habitable zone, there is a risk of abiotic oxygen detection, but this risk becomes negligible for big planets further away from their star. The fact that on the Earth oxygen and indirectly ozone are by-products of the biological activity does not mean that life is the only process able to enrich an atmosphere with these compounds. The question of the abiotic synthesis of biomarkers is crucial, but only very few studies have been dedicated to it (Rosenqvist and Chassefiere 1995; Leger et al. 1993; Lagrange et al. 2009; Selsis et al. 2002).

Cryptic Worlds

On the Earth, photosynthetic organisms are responsible for the production of nearly all of the oxygen in the atmosphere. However, in many regions of the Earth, and particularly where surface conditions are extreme, for example, in hot and cold deserts, photosynthetic organisms can be driven into and under substrates where light is still sufficient for photosynthesis. These communities exhibit no detectable surface spectral signature. The same is true of the assemblages of photosynthetic organisms at more than a few meters depth in water bodies. These communities are widespread and dominate local photosynthetic productivity on Earth. Such worlds could be very interesting Earth analogues that could

be habitats but cannot exhibit a biological surface feature, such as that due to chlorophyll, in the disk-averaged spectrum (Cockell et al. 2009).

Summary

Dedicated future space missions will have the explicit purpose of detecting other Earth-like worlds, analyzing their characteristics, determining the composition of their atmospheres, investigating their capability to sustain life as we know it, and searching for signs of life. These searches for signs of life will be based on the assumption that extraterrestrial life shares fundamental characteristics with life on Earth, in that it requires liquid water as a solvent, has an energy source, and has a carbon-based chemistry. Life on the basis of a different chemistry is not considered here, because the vast possible range of conceivable life-forms might produce signatures in their atmosphere that so far are unknown. We have identified some remotely detectable biomarkers whose presence at significant abundance would strongly suggest a biological origin (e.g., the couples CH₄ + O₂ or CH₄ + O₃ (Lovelock 1975) or N₂O). In addition to searching for signs of life, we need to understand how the observed atmosphere physically and chemically works.

Future Directions

Models of habitable worlds with different parameters (e.g., age, mass, size, composition, temperature, and biota) expand our knowledge of how a habitable planet's spectrum could appear and how robust our definition of biomarkers is. We are just starting to learn how to characterize habitable planets remotely. The results of a first-generation mission will most likely result in an amazing scope of diverse planets that will place our own planet in an overall context.

Definition

Biomineralization is the process by which organisms form minerals, which are called biominerals. It is a widespread phenomenon induced or controlled by a huge diversity of eukaryotes, bacteria, or archaea. There is a very large diversity of chemical compositions and structures for biominerals, including carbonates (e.g., aragonite, calcite), silicates (e.g., opal, authigenic Mg-silicates such as talc), and Fe and/or Mn oxides. Biominerals can be used in the search for traces of ancient terrestrial or extraterrestrial life. They can be used as recorders of paleoenvironmental conditions, especially in paleoclimatology (e.g., corals,

foraminifers). Finally, their unique properties can inspire mimetic strategies intending to design nanomaterials for new advanced technologies.

Overview

Organisms can impact mineral formation at several steps:

1. Organisms can modify actively or passively solution chemistry in their vicinity, by changing pH or the activity of any chemical species. This may raise supersaturation with a mineral phase in the surrounding solution or inside the cells and makes conditions thermodynamically favorable to mineral precipitation.
2. Organisms can impact nucleation, that is, the formation of very small and unstable mineral seeds. They can indeed stabilize these nuclei by providing large surfaces (e.g., cell walls, extracellular polymers) with lower surface tension.
3. Finally, organisms can impact mineral growth. Traditionally, growth takes place layer by layer. Organisms can inhibit crystal growth in certain directions by the production of poisoning molecules, forming minerals with particular shapes. Alternatively, nuclei may aggregate, forming mesocrystals, sometimes with the mediation of an organic matrix (e.g., Sethmann et al. 2006). This mechanism has been increasingly identified in biomineralizing systems, but exact molecular mechanisms remain unknown.

Three types of biomineralization processes have been distinguished in the literature (Dupraz et al. 2009):

1. *Biologically controlled biomineralization* refers to cases in which a specific cellular activity directs the nucleation, growth, morphology, and final location of a mineral, involving specific genes. Many eukaryote biominerals result from this process. Formation of intracellular magnetites in magnetotactic bacteria (Lefèvre

- and Bazylnski 2013) and intracellular carbonates in several cyanobacteria (Benzerara et al. 2014) and *Achromatium oxaliferum* are additional examples.
2. *Biologically induced biomineralization* results from the indirect modification of the chemistry of the environment by biological activity. Several types of microbial metabolism can, for example, modify solution chemistry and induce carbonation, that is, precipitation of carbonate minerals, including photosynthesis, sulfate reduction, urea degradation, ammonification, or denitrification (Castanier et al. 2000).
 3. *Biologically influenced biomineralization* is defined as passive mineralization of organic matter, whose properties influence crystal morphology and composition. Polysaccharides and proteins have been shown to impact biomineralization in many cases (e.g., Obst et al. 2009). The term organomineralization is sometimes used, encompassing biologically influenced and biologically induced biomineralization.

The morphology, structure, and chemistry of prokaryote biominerals have frequently been proposed as potential biosignatures (e.g., Konhauser 1998) and used to infer the presence of traces of life in ancient terrestrial or extraterrestrial rocks such as the Martian meteorite ALH84001 (McKay et al. 1996). For further reading, reviews on various biomineralizing systems can be found (e.g., Bäuerlein 2000; Mann 2001; Weiner and Dove 2003; Benzerara and Menguy 2009; Benzerara et al. 2019).

Biomorphs

Juan Manuel García-Ruiz

Instituto Andaluz de Ciencias de la Tierra, CSIC-Universidad de Granada, Armilla, Granada, Spain

Keywords

Biomimetic · Self-organization · Life detection · Early life · Barium carbonate · Calcium carbonate

Definition

Biomorphs are abiotic mineral structures displaying morphology characteristics of living organisms, i.e., shapes described by fractal branching and continuous curvature. They must form under plausible geochemical conditions of the Earth or other planets and moons through natural physicochemical processes without life intervention. Biomorphs may emulate amazingly well the morphology of early life forms and some of the oldest remnants of life on our planet. They are, therefore, relevant to the problem of life detection on Earth and elsewhere.

History

The term was coined by García-Ruiz to describe biomorphic polycrystalline structures of barium carbonate and silica (García-Ruiz 1994). “Biomorph” means abiogenic mineral patterns that share with life morphology. The name was inspired by the paintings of Desmond Morris and the virtual entities devised by Richard Dawkins in the book “The blind watchmaker.”

Overview

The ability of living systems to engineer complex shapes has led us to believe in the existence of a boundary separating the realm of biology from the realm of inorganic minerals. Such a belief profoundly influences the use of morphology as a critical criterion for biogenicity in primitive life detection studies (Buick 1990; Schopf 1993). However, bizarre as it might seem, purely inorganic processes can also yield self-assembled complex structures with non-crystallographic symmetry that mimics extremely well the shape of early living organisms (Fig. 1) (García-Ruiz 1999; Brasier and Wacey 2012). The most interesting of these processes in terms of morphological emulation and geochemical plausibility is the one leading to the precipitation of alkaline-earth carbonate from

alkaline silica-rich solutions. The synthesis is straightforward, requiring only a source of carbonate ions (e.g., atmospheric CO₂), strong alkaline aqueous solutions, silica, and alkaline-earth cations (Ba and Sr, Ca). Under these alkaline conditions, the precipitation of alkaline-earth carbonates (witherite, strontianite, or monohydrocalcite/aragonite) is coupled to silica interactions yielding crystal aggregates made of thousands of nanocrystals exhibiting self-assembled noncrystallographic morphologies (García-Ruiz et al. 2009). These structures share with life complexity, morphology, hierarchy, and self-organization. Their morphologies are highly reminiscent of the shape of primitive organisms, but the precipitates are purely inorganic in origin and form without the involvement of biological compounds or living organisms. This is the reason why they were named silica-carbonate biomorphs. The extreme conditions of pH and silica concentration required for silica-carbonate self-organization are rare but occur in contemporary environments such as those linked to serpentinization hydrochemistry and soda lakes (García-Ruiz et al. 2017). However, these nowadays bizarre geochemical conditions are thought to be widespread in early states of the history of the Earth, particularly during the Hadean (Saladino et al. 2019; García-Ruiz et al. 2020). However, so far, silica-carbonate biomorphs have not been clearly identified in rocks.

Silica biomorphs emulate the shape of primitive organisms to such a degree that for many years they were questioned based on possible biological contamination of the experiments to synthesize them. Nowadays, it is widely accepted that silica-carbonate biomorphs are formed by pure inorganic mechanisms (Kellermeier et al. 2012), and that they do so under geochemical conditions similar to those leading to chert precursors, where the putative Archean microfossils were embedded (García-Ruiz et al. 2003). The existence of silica biomorphs has questioned the use of morphology as an unambiguous criterion for the detection of primitive life remnants. More precisely, the claim

Biomorphs, Fig. 1 A selection of scanning electron micrographs of silica-witherite biomorphs. (Adapted from Camerup 2007 Scale bars = 15 microns)

is that morphology does not contain definitive information on morphogenesis (García-Ruiz et al. 2002). This assertion could come as a shock to biologists who used to identify fossils by their morphologies, so different from the morphology of minerals and rocks. However, it must be remembered that what we use to identify fossils of ammonites, trilobites, or dinosaurs as remnants of life is not morphology but comparative anatomy, an idea introduced by Cuvier in the nineteenth century. When looking for the oldest remnants of life, the problem is that they are tiny pieces of rock, with poor or no compartmentalization at all, namely microspheres, microrods, tubules, septated tubular shapes, simple helicoids, discoid shapes, and a few other simple shapes. Therefore, it is impossible to apply comparative anatomy to these putative fossils of early life. Thus, when identifying the physical structures of possible oldest remnants of life on this planet or in extraterrestrial bodies, we

have nothing else than morphology. This made the unambiguous differentiation of actual life remnants from inorganic biomimetic counterparts a task that must be performed with caution (van Zuilen et al. 2002; Rouillard et al. 2018; Javaux 2019). The study of silica biomorphs has revealed a new morphogenetic mechanism capable of creating crystalline materials with positive or negative constant curvature and biomineral-like textures, which lead to the design of new pathways toward concerted morphogenesis and bottom-up self-assembly created by a self-triggered chemical-coupling mechanism. The potential interest of these fascinating structures in Earth Sciences has never been fully explored, mostly because of their complexity and multidisciplinary nature (Fig. 2).

While the term “biomorphs” was coined for the above-described carbonate precipitation induced by silica, the trend in paleontological and astrobiological studies nowadays is to call

Biomorphs, Fig. 2 Optical micrographs of silica-witherite biomorphs before and after exposure to organic species, all taken under identical illumination: (a) inorganic biomorph as synthesized; (b) biomorph after

biomorphs to any abiotic mineral shapes that may be an alternative explanation to biological remnants of early life (Cosmidis and Templeton 2016; Dodd et al. 2017).

Biopan

René Demets

ESTEC (HSF-USL), Noordwijk, The Netherlands

Keywords

Exposure experiments · Radiation biology

Definition

Biopan is a pan-shaped exposure facility for experiments in the domains of astrobiology, radiation biology, and radiation dosimetry (Demets et al. 2005). Externally mounted on unmanned recoverable satellites of the Foton type, Biopan flies 2-week missions in low Earth orbit at 63.0° inclination, allowing exposure of biological samples to the harsh space conditions. Six flights have been completed between 1992 and 2007 with up to ten different experiments per flight. Biopan carries its experiment packages (total mass 4 kg max.) on two mounting plates (total surface area 1080 cm²).

Overview

In orbit, the hinged lid of Biopan is opened by telecommand whereupon the experiments are freely exposed to the space environment. At the end of the flight, the lid is hermetically closed and locked. During reentry into the atmosphere, Biopan and its contents are protected against the frictional heat by an ablative heat shield. Biopan is equipped with a variety of sensors to monitor and record the environmental history of the test samples. Included are ultraviolet (UV) sensors, a radiometer, and a set of eight thermistors to measure the experiment temperatures. The sensor data are stored on board and retrieved after landing. The temperature profile of the experiments is selectable. A noncontrolled mode can be chosen with temperatures freely oscillating between ≤ -20 °C and $\geq +10$ °C, in sync with the alternating periods of solar illumination and shadowing in orbit. Alternatively, by using electrical heaters and thermal blankets, a stable temperature can be provided with a fixed set point

in the 10–25 °C range. Organic molecules, bacterial spores, ► [archaea](#), plant seeds, ► [lichens](#), and tardigrades have been exposed in Biopan to a combination of solar UV, space vacuum, space radiation, wide temperature fluctuations, and weightlessness. Biopan carries reference samples, which are kept under identical conditions but shielded against UV. Additional control samples are maintained on ground. The typical operational cycle of Biopan includes experiment integration at 1 week before launch, 2 weeks of orbital flight, and return of the experiments to the investigators at 4 days after landing. Biopan was designed and built for ESA by Kayser-Threde (Munich, Germany) with Kayser Italia (Livorno, Italy) responsible for the flight software and the electronics. The heat shield is manufactured by TsSKB-Progress (Samara, Russia).

Definition

Biopolymers are mostly organic molecules that are composed of repeating monomers and produced by living organisms. Homopolymers are such molecules that are composed of one type of monomer, while heteropolymers are composed of more than one type of monomer. Such ► [polymers](#) may either be a repeating unit of two or more monomers or may be more heterogeneous, complex, and often branched.

Overview

There is a wealth of examples of biopolymers important for the organisms that produce them and for the ecosystems they inhabit. Polynucleotides and polypeptides are the key to life. Polynucleotides (deoxyribonucleic acid, DNA, and ribonucleic acid, RNA) are the carriers of information in cells and are responsible for the translation of this information into polypeptides. Polypeptides are proteins and enzymes that are composed of amino acids that are polymerized through peptide bonds. Enzymes catalyze most metabolic reactions in the cell. Glycogen, chrysolaminaran, and starch are examples of branched and linear polyglucoses that serve as carbon and energy storages in a variety of organisms. Polyhydroxyalkanoates (PHA), such as polyhydroxybutyrate (PHB), also serve as reserve compounds in many bacteria. These compounds have found application as biodegradable plastics. Cyanophycin is a polymer also known as multi-L-arginyl-poly-[L-aspartic

acid]. It serves as nitrogen storage, and although it was first discovered in cyanobacteria (therefore the name), it also occurs in other bacteria. This polymer has found application as a pharmaceutical. Chitin is a linear homopolymer of *N*-acetylglucosamine. Chitin and cellulose (a glucose polymer) share a similar structure. Chitin is a component of the cell walls of arthropods and most fungi and is also synthesized by some diatoms, but is not known in bacteria or archaea. Cellulose is a typical plant ► [cell wall](#) component but is also synthesized by some bacteria, notably by cyanobacteria. Peptidoglycan (murein) is a biopolymer of *N*-acetylglucosamine and *N*-acetyl-muramic acid, which serves as the main cell wall component in bacteria and some archaea (the latter possess a slightly different polymer known as pseudo-peptidoglycan). Polyphosphate is an inorganic polymer of orthophosphate and occurs in all three domains of life. In bacteria, polyphosphates may serve as storage of phosphorus and/or energy. Silicate is a mostly inorganic polymer of silicon although it is normally associated with organic matter. Silicate is the main component of the frustules of diatoms. Probably the most diverse and complex biopolymers are exopolymers. These are complex polymeric carbohydrates with associated glycolipids, proteins, and nucleic acids, as well as a variety of uronic acids, pyruvate, sulfate, and carboxylic groups. They may serve as the sheath of microorganisms or be extruded as mucilage in the outer environment and have a variety of functions.

Definition

Bioprecipitation refers to the process of formation of mineral phases (bioprecipitates or biominerals) by organisms. Cells or associated extracellular polymers can serve as nucleation surfaces and/or alter the chemical composition of fluids and raise the supersaturation of the solution with a mineral phase. Alternatively, bioprecipitation has been used in meteorology to refer to the nucleation of ice by bacteria in clouds resulting in snow or rainfall.

Definition

A biosensor is a compact hybrid device incorporating a biological receptor in direct contact with a transducer (the term “biosensor” derives from this combination). The biological element specifically recognizes a substance (chemical or biological) in a sample, thereby inducing a change in the transducer, which delivers a signal proportional to the concentration of the substance (see Fig. 1). The main advantages of biosensors are the selectivity and sensitivity of the analysis. In addition, biosensors can supply real-time and online information. Biological elements employed can be enzymes, antibodies, DNA, whole cells, or tissues, for example. Depending on the physical change observed, transducers could be electrochemical, optical, piezoelectric, acoustic, magnetic, or nanomechanical.

Biosensor, Fig. 1 Scheme of a biosensor device

Overview

Biosensor is a general term for a wide range of analytical devices that measure the presence or concentration of biological or chemical molecules in complex samples by translating a biomolecular interaction at the transducer surface into a quantifiable physical signal. When the biospecific interaction takes place, a physicochemical change is induced, as, for example, a redox, mass, resonant frequency, absorption, or refractive index change. The aim of a biosensor is to produce discrete or continuous signals that are proportional to the concentration of a single analyte or a related group of analytes. The biological element is capable of sensing the presence, activity, or concentration of the substance in a solution. Substances capable of being analyzed with biosensors range from protein biomarkers, toxins, antigens, drugs of abuse, pesticides, peptides, proteins (IgG, albumin, insulin, etc.), hormones, vitamins, antibiotics, organic molecules (glucose, lactose, cholesterol, urea, etc.), DNA and DNA single mutations, RNA, microRNA, epigenetic marks, cancer cells, pathogenic microorganisms, and many others.

The first demonstration of a biosensor dates from 1962, when enzyme electrodes for glucose sensing were developed by L. C. Clark (USA). Since then, an intensive effort has been focused on biosensor research and development, a significant output of which was the commercial launch of the glucose biosensor in 1975. The glucose biosensor has become a landmark in the diagnostics field, thereby allowing millions of diabetics to test, in any place and at any time, their glucose level in the blood. Substantial work on achieving reliable biosensors began in the 1980s, and since then, many developments have been demonstrated. Biosensing technology has been a very active research field both in academic and in industrial laboratories during the last decades. But, until now, only a limited number of biosensors have achieved the stringent requirement for being commercialized. This is mainly due to the poor stability of the biological receptor once it is in contact with the transducer, as it must be stable under variable conditions of pH, temperature, humidity, and ionic strength.

The use of biosensor devices has clear advantages in analytical chemistry. The main characteristics of biosensors are high sensitivity and

selectivity. In addition, biosensors can provide rapid, direct, and cost-effective analyses, ease of operation, high accuracy, and wide detection range using a minimum volume of sample and reagents. This technology avoids the expensive, complex, and time-consuming procedures typically employed in standard analytical evaluation.

In order to obtain reliable biosensor devices, there are two crucial steps: (i) the design and fabrication of a highly sensitive physical transducer, that is, a device capable of efficiently transforming the biomolecular reaction into a measurable signal, and (ii) the stable and reliable biofunctionalization of the physical transducer with the appropriate, selective, biological receptor (protein, DNA, cell, aptamer, etc.). The biosensor research and development area is highly multidisciplinary because several aspects need to be considered to successfully achieve the device, such as the transduction modality used, fluidic design (most of the biosensing analyses are performed in liquid), surface biofunctionalization, detection format (direct, indirect, sandwich-type, competitive binding), and data processing and analysis.

Basic Methodology

The possible combinations of different bioreceptors and transducers result in a vast range of biosensor types. Depending on the bioreceptor, the transducer, or the type of detection, biosensors can be classified into different types and subtypes. It is important to point out that the selection of the most suitable combination of bioreceptor/transducer/type of detection is dictated by the application itself, which depends on the type of substance to be detected and the complexity of the sample which contains the substance to be evaluated.

Types of Detection

Two main types of detection can be employed: “label” and “label-free.” In the “label-free” scheme, the original and unmodified analyte is detected in a direct manner. In the “label” approach, the analyte is tagged with a label which acts as an indirect indicator of the presence

of the molecule. In general, the “label” approach results in a higher sensitivity of analysis, while the “label-free” approach is direct, is rapid, and avoids the manipulation or degradation of the analyte. Each detection method has advantages and disadvantages and the method employed should be selected according to the foreseen application.

Classification by Bioreceptor Layer Type

Depending on the bioreceptor, biosensors can be divided into two main types: catalytic biosensors and affinity biosensors. In catalytic biosensors, the receptors are able to recognize (bio)chemical species and transform them into a product. This type of biosensor is mostly represented by enzymatic biosensors, but whole cells or tissue receptors also fall under this category. Affinity biosensors use the specific capabilities of an analyte to bind to a biorecognition element. Immunosensors (based on specific interactions between an antibody and an antigen) or DNA biosensors (based on the affinity between complementary oligonucleotides) are the main examples of affinity biosensors. Biomimetic receptors based on engineered molecules as aptamers or molecular imprinted polymers have emerged during the last years as an attractive alternative to biological receptors, although they have not achieved yet the same specificity than the natural receptors and they are only suitable for some specific applications.

Classification by Transducer Type

Depending on the transducer employed, biosensors can be divided into the following main types: electrochemical biosensors, optical biosensors, piezoelectric biosensors, magnetic biosensors, and nanomechanical biosensors. Electrochemical biosensors are based on changes in electrical currents or potential across electrodes when the biosensing reaction involves redox changes. They are the simplest and most developed biosensors. They can be amperometric (based on the measurement of the current resulting from the electrochemical oxidation or reduction of electroactive species), potentiometric (based on the determination of the potential difference between an indicator and a reference electrode (such as ISFET devices)), or conductometric (based on a change in conductance (such as measured by

interdigitated electrodes)). Piezoelectric biosensors are based on the piezoelectric effect: the frequency of a resonating crystal changes when molecules are adsorbed on top of the crystal. Surface acoustic wave systems and quartz crystal microbalances are the main examples of piezoelectric devices.

In optical biosensors, the biorecognition event results in a change in optical properties such as a variation in the emission properties (luminescence), in the absorption coefficient, or in the refractive index. This variation induces a change in some of the characteristics of light (wavelength, intensity, polarization, phase velocity) which can be detected using techniques as emission, absorption, fluorescence, evanescent wave detection, or polarimetry. Many optical biosensors have been developed because they frequently exhibit higher sensitivity than other transducer types. One of the most successful label-free and commercially accepted optical biosensors is the surface plasmon resonance (SPR) sensor that is based on an evanescent wave interaction. Localized surface plasmon resonance (LSPR) based on metal nanostructures has gained attention in the last years. Other optical biosensors make use of optical waveguides as the basic element for light transmission, such as optical fibers or integrated optics-based waveguides, including interferometers (Mach-Zehnder, Young, bimodal interferometers), microcavities (as microring resonators), and grating- and photonic crystal-based structures. Other optical biosensors include those based on porous silicon, silicon photonic wires, or resonant bicells.

In nanomechanical sensors, the specific biorecognition on the cantilever surface results in a nanomechanical response, which produces a cantilever bending of few nanometers and a shift in the resonant frequency. In this way, microcantilevers translate the molecular reaction into a nanomechanical motion, which is commonly detected using optical or piezoresistive readout. Nanomechanical sensors achieve a high level of sensitivity and are amenable for array multiplexing and integration in compact platforms.

Biofunctionalization

Biofunctionalization is the process of immobilizing the receptor biomolecules onto the transducer surface to provide the required

biospecificity of the biosensor. The bioimmobilization process must maximize the sensitivity and must supply a reproducible layer and must ensure optimal coverage density of the receptor, proper receptor orientation for efficient kinetics, minimal background and nonspecific adsorption, and long-term stability. Amongst the various bio-immobilization approaches, the most commonly used are physical adsorption, covalent binding, and affinity-based (as avidin/biotin, His-Tag systems, protein A/G for antibodies) entrapment (physical or covalent) within host matrices (e.g., polymers, polymeric hydrogels, and sol-gels). Usually, covalent binding to the substrate is the preferred route for most bioreceptors through the use of self-assembled monolayers, but the most suitable technique depends on the bioreceptor type and the sample to be evaluated.

Whatever the immobilization technique employed, a previous chemical activation of the sensor surface is mandatory. Silicon-, silicon oxide-, and silicon nitride-based surfaces can be functionalized using the well-known silane chemistry. Gold surfaces are normally functionalized using thiol chemistry.

Applications

The fields of application for biosensors are almost endless. Applications for these devices include clinical diagnostics (including personal health monitoring), basic research in life sciences, drug research in the pharmaceutical industry, online screening of water quality for both household and industrial use, control of industrial processes, veterinary diagnostics, quality control in the food and beverage industry, detection of harmful substances, military and homeland security or environmental monitoring, and many others. The most significant applications are related to the clinical diagnostics field, mainly due to the great success of glucose biosensors since their invention. Indeed, glucose biosensors account for about 85% of the entire biosensor market. In the astrobiology area, biosensors are useful tools for detecting biomarkers or biosignatures of extant or extinct life which could be produced in biotic or abiotic processes (such as bacteria strains, cells,

extracellular materials, isolated macromolecules or biomarkers, etc.).

Future Directions

The ultimate aim in biosensor technology is the achievement of a fully integrated, low-cost, portable, and reliable lab-on-a-chip platform, able to simultaneously detect and identify hundreds of substances in real time with high sensitivity, even at the single molecule level and connected through a wireless scheme to a central operational station or hospital database. Therefore, the major future objectives in biosensor technology will be to achieve higher sensitivity, to reduce sample volume and reagents by miniaturization at the micro-/nanoscale, to increase the number of substances detected within the same sample, to develop devices of high multiplexing capabilities for analyzing an elevated number of substances in parallel, and to develop wearable biosensors and biosensors suitable for implantation in the human body. Other important aspects to be considered in the future are issues associated with the commercialization of biosensors for relevant applications, which still face significant technological hurdles. Development cycles tend to be long and commercial success remains limited. The main issues in biosensor technology, such as the stability and reliability of the biorecognition layer, still need to be surpassed.

Definition

Biosignatures are molecular, mineral, or isotopic patterns that can be unambiguously interpreted as evidence of extant or extinct life (Slater 2009). However, fossilized biosignatures are not immutable but prone to degradation during diagenesis and ► [metamorphism](#) and may become difficult to distinguish from signatures of abiogenic compounds (e.g., García-Ruiz et al. 2003; Pasteris and Wopenka 2003; McCollom and Seewald 2006). Nevertheless, from the multiscale characterization of organic-rich ► [metamorphic rocks](#) using advanced synchrotron-based micro ► [spectroscopy](#) techniques, Bernard et al. (2007, 2010) have shown that high-grade metamorphism might not totally erase structural and chemical bio-features, at least at the sub-micrometer scale.

Overview

Understanding the physical and chemical evolution of life relies on the ability to decipher preserved evidence in the rock record, a.k.a. fossilized biosignatures (Seckbach and Walsh 2008; Slater 2009). However, the combination of biological, chemical, and physical factors during taphonomic

processes and deep burial inevitably alter the chemical, structural, and isotopic fidelity of such fossilized biosignatures (Schiffbauer et al. 2007). In addition, abiogenic processes may form disordered carbon-dominated precipitates displaying morphologies and signatures quite similar to biogenic objects (García-Ruiz et al. 2003; Pasteris and Wopenka 2003; McCollom and Seewald 2006). Therefore, unambiguously identifying biosignatures within metamorphic rocks has been generally believed to be extremely difficult, if not impossible, except in very rare cases such as the exceptionally well-preserved Burgess Shale ► [fossils](#) which experienced greenschist facies metamorphism (Powell 2003). Recently, the analytical improvements of microspectroscopy techniques in general and synchrotron-based techniques in particular (see Templeton and Knowles 2009 for a review) have allowed the chemical and structural characterization of metamorphic organic matter down to the nanometer scale. Altogether, these studies have shown that even high-grade metamorphic rocks may retain morphologically and geochemically recognizable traces of life, depending notably on the original biochemical nature of the ► [biopolymer](#) (Bernard et al. 2007, 2010).

In the long term, physical biosignatures have a greater chance of preservation than complex organic markers. Metamorphic degradation of ► [organic molecules](#) is associated with an aromaticity increase, mainly by the release of heteroelement-containing functional groups as CO₂, N₂, and H₂S and by the elimination of aliphatic groups as CH₄. Organic molecules which have undergone restructuring during early diagenesis to become resistant cross-linked aliphatic or aromatic macromolecules (a.k.a. geopolymers) and those which have been closely associated to minerals (such as carbonates, sulfates, and clays) will have a greater chance of long-term preservation. The isotopic composition of organic compounds is relatively stable, to the extent that basic molecular skeletons are preserved. Otherwise, the effect of thermal metamorphism on organic matter is to form isotopically lighter volatile species and isotopically heavier residual refractory solids. In conclusion, although biosignatures might be partially preserved during metamorphism, a great

deal of caution must be implemented and multiple lines of evidence (morphological, ultrastructural, as well as geochemical) must be sought during their analysis and interpretation.

Ecosphere, Gaia

Definition

The biosphere is a concept initially created by the prominent geologist Edward Suess to define the upper part of the Earth's lithosphere intricately associated with life (Smil 2003). Later on, the Russian biologist Vladimir Vernadsky realized the actual dimension of the impact of life on Earth and linked the biosphere to a natural entity intimately associated with global geochemical cycling of matter and energy within the terrestrial crust (Vernadsky 1998). According to this last conception, the biosphere can be understood as a complex, natural entity resulting, at a global planetary scale, from the interactions between all life forms and the different reservoirs of matter and energy like the geosphere, hydrosphere, and atmosphere (Smil 2003). Based on this concept, the British scientist James Lovelock envisaged the biosphere as an organism of planetary scale, Gaia, which rules the planet's main physical and chemical parameters through a series of intricate feedback mechanisms (Lovelock 2000).

Overview

Under a formal ecological approach, the biosphere can be defined as a global biological system that arises from the integration of all biocenosis (Lévêque 2003), ranging from those sustained by autotrophs that can range from primary photosynthesizers to chemolithotrophic producers as found in deep crustal regions or in the hydrothermal systems. In this sense, the ecosphere would include the biosphere as the biotic component of the planetary ecosystem, as in the same way, biocenosis accounts for ecosystem (Huggett 1999). As the biosphere merged early in time with the geochemical cycles that are operating in our planet, sometimes it is challenging to separate the living

systems from the different nonbiological planetary reservoirs such as the atmosphere, the hydrosphere, and the geosphere. The complex pathways of exchanging matter and energy between the biosphere and the planet led to the emergence of feedback mechanisms that control the environment's physical and chemical variables at regional and global scales. One paradigmatic example is the temperature and pH control in the oceans (Orr et al. 2005; Knoll et al. 1996) through the uptake and sequestration of CO₂ that is transformed into biomass and carbonates, and which is later buried in the form of organic matter, or the carbonates themselves. The same kind of global feedback is controlled by the cycling of compounds bearing nitrogen and sulfur, which induce physical and chemical changes in the Earth's atmosphere by photochemical reactions occurring in the troposphere (Seinfeld and Pandys 2006). They regulate the thermal conditions on the Earth's surface by controlling the planetary albedo through the release of dimethyl sulfide that oxidizes to SO₂. Interestingly, the biosphere also controls the environmental conditions by controlling the thermal and hydric balance in a region. It commonly happens through the structure and composition of the large communities of terrestrial woodlands, which interact with the water cycle to modify the thermal and hydric conditions at regional and, therefore, global scales (Rodríguez-Iturbe and Porporato 2004). The GOE driven by the photosynthesizers activity during the Late Archean-Early Proterozoic resulted in, at a greater scale, a global process of environmental control. As a result, the biosphere becomes more diverse and takes control of new Earth regions through the oxygen cycle that has a large impact on the Earth's crust. The emergence of the oxygen cycle led to large-scale ecological succession starting with a few low-specialized colonists and ending in the formation of different diverse ecosystems sustained by very specialized organisms adapted to a wide variety of niches. Consequently, microbially-mediated oxygenation combined with global geological events (Knoll 2003) triggered diversity and environmental changes that affected the ocean habitats and led to the colonization and

environmental control of the early Earth's continental areas. The total biosphere biomass has been estimated of being around 550 gigatons (Gt) of carbon ($1 \text{ Gt} = 10^{15} \text{ g}$), where plants hold about 450 Gt, which equals the 80% of the total biomass on Earth (Bar-On et al. 2018). Some biomass estimates for the Paleozoic woodlands show that they stored a similar magnitude of carbon as the Amazonas and Congo tropical forests (Fernández-Remolar et al. 2018). If those calculations are right, it suggests that by the end of the Devonian (about 360 Ma), the total terrestrial biomass was comparable to the biomass stored by the modern biosphere.

Biostabilization

Nora Noffke
Old Dominion University, Norfolk, Virginia,
USA

Synonyms

[Microbial sediment fixation](#)

Definition

Biostabilization is the fixation of clastic sediment by biofilms, microbial mats, and their extracellular polymeric substances (EPS) in natural aquatic settings (Paterson 1997). Three main effects of biostabilizations can be distinguished (Noffke 2010). Type 1 – microbial reduction of sediment

erodibility. Type 2 – allowing the flexible deformation of a sediment surface composed of loose grains that without the presence of a biofilm-matrix, would disintegrate upon pressure. Type 3 – smoothing and sealing of the sedimentary surface reducing gas and fluid exchange between sediment and atmosphere or water. Biostabilization is one of four mechanisms that lead to the formation of microbially induced sedimentary structures (MISS) such as gas domes, roll-ups, and mat chips.

History

Biostabilization of clastic deposits by microbial mats was studied in tidal flats of the North Sea. Führböter and Manzenrider (1987) used a portable flume chamber placed on microbial mats to quantify the resistance of the microbenthos against erosion by water current. Paterson (1997) conducted laboratory experiments that showed the mechanics of microbial stabilization.

Biostack

Gerda Horneck
DLR German Aerospace Center, Institute of Aerospace Medicine, Radiation Biology, Köln, Germany

Keywords

Biological radiation effects · Cosmic rays · Heavy ion hits · HZE particles · Nuclear track detectors

Synonyms

[Biobloc](#)

Definition

The Biostack concept allows studying the biological effects of single heavy ions of cosmic rays. Each Biostack device is composed of a stack of visual track detectors (e.g., nuclear emulsions, cellulose nitrate, and polycarbonate) with layers of biological objects in resting state sandwiched between them. After exposure to the outer space, the track detectors are developed, the trajectory of each heavy ion is localized relative to the site of the biological object, and the physical data of each particle are correlated with the observed biological effects along its path.

History

The Biostack program has been developed in the late 1960s under the auspices of the Council of Europe within the Working Group on Space Biophysics and has been performed in international cooperation by scientists from Europe, Russia, and the USA. Biostack experiments were flown on the NASA missions Apollo 16 and 17 (1972), Apollo-Soyuz Test Project (1975), and the ► [Long Duration Exposure Facility](#) (1984–1990), on ESA/NASA missions Spacelab

1 (1983) and Spacelab IML-2 (1994), on the German/NASA mission Spacelab D2 (1993), on the ESA mission ► **EURECA** (1992–1993), and on ESA/Russian missions of the Biocosmos and Foton series (1992–1994). The Biostack program was managed by Horst Bücker and Günther Reitz, both from the German Aerospace Center (DLR), Germany.

Overview

With the beginning of human space flight, health effects from exposure to cosmic rays became a concern, and radiation protection guidance has been required. The heavy ions of cosmic radiation, the so-called ► **HZE particles**, i.e., particles of high (H) atomic number (Z) and high energy (E), are of special concern. To understand the ways by which single particles of cosmic radiation interact with biological systems, the Biostack concept was developed to precisely localize the trajectory of an HZE particle relative to the biological object and to correlate the physical

data of the particle relative to the observed biological effects along its path (Fig. 1). A large variety of biological specimens, such as viruses, bacterial ► **spores**, plant seeds and animal eggs, and cysts, allowed the evaluation of radiation effects at different levels of biological organization and at different radiation sensitivities. The following biological effects were ascribed to the passage of a single HZE particle:

- In seeds of *Arabidopsis thaliana* or *Nicotiana tabacum*, hit by an HZE particle in their shoot meristem, development was significantly disturbed, as demonstrated by up to 90% loss of germination (early lethality) or embryo lethality. Seedling abnormalities, such as hypertrophy or deformation of cotyledons, hypocotyl, or root, or chlorophyll deficiency, occurred with high frequency as a consequence of a passage of a single HZE particle close to the shoot or root meristem. In *Lactuca sativa* seeds, hit by an HZE particle, multiple chromosomal aberrations developed at high frequencies. *Zea mays* seeds, flown on ASTP,

Biostack, Fig. 1 The Biostack concept to localize biological effects produced by single HZE particles of cosmic radiation; Biostack experiments were flown onboard of

Apollo 16 and 17; ASTP; Spacelab 1, D2, IML-1, and IML-2; LDEF; Cosmos 1887 and 2004; and EURECA (Photo credit DLR)

developed large yellow strips in all leaves as somatic mutation.

- In 90% of the mosaic eggs of the brine shrimp *Artemia salina* hit by an HZE particle, hatching, characterized by release of a free-swimming nauplius, was inhibited. Anomalies of the body or extremities appeared approximately ten times more frequently than in the ground controls. Likewise, hatching of the Indian stick insect *Carausius morosus* from eggs, hit by a cosmic HZE particle, was significantly reduced. Malformations were increased in individuals having developed from eggs hit. They were characterized by a curved abdomen, fused segments, or shortened legs.
- Spores of the bacterium *Bacillus subtilis* were inactivated well beyond 1 μm from the HZE particle trajectory, whose distance would roughly correspond to the dimensions of a ► [spore](#), thereby pointing to a long-ranging effect of HZE particles.

Quantifying various genetic and developmental disturbances caused by individual HZE particles of cosmic radiation, the Biostack data are of relevance for assessing the radiation risks for astronauts, especially during exploratory missions, as well as for estimating the likelihood of ► [lithopanspermia](#), i.e., the interplanetary transfer of microorganisms within rocks.

Bipolar Flow

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Keywords

Molecular flow · Star formation

Definition

Bipolar flows are a phenomenon associated with young stars still embedded in their parent ► [molecular clouds](#). There are two kinds of flows – jets and molecular outflows. The first represent high-speed stellar wind gas, ejected into two narrow streams. The second are broader cones of more slowly moving cloud gas. Each molecular outflow is driven by a jet running down its central axis. What is seen most prominently in the jets are shock waves created when the wind runs into either ambient cloud gas or slower gas ejected earlier. Neither the launching of the wind nor its collimation into jets is well understood.

Overview

It has long been known that massive stars emit strong winds that drive back nearby gas. Since these objects are all relatively young, there is often such a gaseous environment, the remnant of the cloud that formed the star itself. In the 1980s, astronomers were surprised to discover that even young stars of solar mass and below drive vigorous outflows. Each outflow appears as two opposite streams (hence “bipolar”) emanating from the central object. In the youngest examples, the star is so embedded in ambient dusty gas that it is optically invisible. Even in such cases, however, bipolar outflows are present. The flows probably play a key role in clearing away remaining material in star-forming molecular clouds. Despite extensive study, the physical mechanisms underlying both their launching and collimation remain mysterious.

Flows generated by young stars have two components – jets and molecular outflows. Both have bipolar morphologies. Otherwise, their properties are very different, undoubtedly reflecting their distinct origins. Stellar jets consist of gas emitted at high speed into a narrow opening angle. A typical jet speed is 300 km/s, which is also the magnitude of the escape velocity from the stellar

surface. The gas has a temperature of 10,000 K. What we observe most prominently are shock waves created when this high-speed gas rams into other material. These shock waves, which radiate in a variety of spectral emission lines, are called Herbig-Haro objects. Discovered in the 1950s, the shocks appeared as isolated, glowing patches. Thirty years later, astronomers detected narrow, faint strands linking the bright knots and leading back to a young, embedded star. Each arm of a stellar jet has a length of about 0.1 pc. Individual Herbig-Haro objects can be detected much farther out, up to several parsecs from the driving source.

Molecular outflows are broader swathes of much slower and cooler gas. They exhibit the same bipolar morphology and axis orientation as jets. Indeed, it is now believed that every molecular outflow has a jet running down its center. Gas in the broader outflows moves at speeds of typically 10 km/s, and most of its mass has a temperature of about 10 K. Since this temperature also characterizes molecular clouds, the broader outflows are thought to represent cloud material being pushed outward by the jet. This relatively cold gas is observed through the radio emission of molecules in the cloud. The dominant species, molecular hydrogen, is a weak emitter at these low temperatures, so astronomers generally utilize CO, which has a strong spectral line at a wavelength of 2.6 mm. Smaller amounts of much warmer gas have been detected using other tracer molecules, such as ammonia.

Since stellar jets glow mainly at optical wavelengths, they are easily obscured by dust in the molecular clouds that lie near the driving stars. To see a jet, the star must be near the surface of the cloud. Sometimes, the cloud has been partially ablated by ultraviolet radiation from a nearby massive star, revealing the young, low-mass star and its jet. The millimeter radio emission used to detect molecular outflows, however, easily penetrates interstellar dust. Thus, these broader flows are relatively easy to find, and hundreds of examples exist. In contrast, there are still only a few dozen clear detections of stellar jets. The red-

shifted arm of the jet, which is penetrating back into the molecular cloud away from the observer, is often considerably fainter but has been detected in most cases.

The high-speed material in stellar jets must represent the actual wind being emitted by the star or the inner portion of its circumstellar disk. The rough match of the wind speed and the stellar escape velocity occurs in other examples of winds from stars over a broad range of masses and ages. How the wind is launched in this particular case is not clear. The wind from our Sun is pushed outward by the hot gas at the base of the solar corona. The mass transport rate in a young stellar jet is higher by 6 orders of magnitude, and thermal pressure is inadequate. It is generally agreed that the wind is tapping rotational energy. The star, which is indeed rapidly rotating, also contains a strong magnetic field. The wind could be flung out along the magnetic field lines, a process which also occurs in our Sun. If this is the basic process, then the jet is also carrying off angular momentum, causing the star to slow its rotation. The outflow could also facilitate accretion of inner disk material onto the star.

The bright knots (Herbig-Haro objects) observed along jets mark locations where high-speed gas encounters material moving at lower velocity. But what exactly is this target material? In a few cases, it is clear that wind gas is impacting the ambient molecular cloud. There are some well-documented examples, however, of the knots being spaced symmetrically around the central star. No external cloud could possess such a high degree of symmetry. Hence, most shocks must arise in a different way.

An important clue comes from observing the space motion of Herbig-Haro objects; images taken a few decades apart show a marked shift, indicating speeds of several hundred kilometers per second. This speed is similar to that detected in the main body of the jet, which we have said represents stellar wind material. On the other hand, the spectral emission lines from the knots indicate that the shocked material is largely neutral so that gas enters the shock front at speeds of only about 30 km/s.

The explanation is that incoming material is hitting not a static environment but one already in motion. That is, the shocks arise when relatively fast wind gas encounters slower gas that was emitted earlier. Thus, the pattern of knots effectively constitutes a record of temporal wind variations, and the symmetrical patterns observed are neatly explained. The inferred fluctuations in wind speed are of order 10%, with associated periods ranging from decades to millennia.

The most mysterious aspect of stellar jets is their remarkable degree of collimation. Most jets have an aspect ratio (length to width) of about 100 to 1. One popular idea is that the rotating wind material twists up in its internal magnetic field. A twisted field exerts an inward force along the central axis. Perhaps this force keeps the jet from diverging. On the other hand, twisted magnetic fields created in the laboratory are unstable to reconnection. So are the twisted flux loops that protrude from the solar surface; their reconnection gives rise to X-ray flares. Researchers are using numerical simulations to see if the more vigorous outflows along interstellar magnetized jets are more stable.

An alternative notion is that the expanding jet creates shocks in the surrounding molecular gas. These so-called reflecting shocks effectively bend the flow back toward the axis. The converging flow then creates another pair of shocks and diverges outward once more. Alternating pairs of reflecting shocks are commonly seen in supersonic flows on Earth, such as the exhaust of a rocket.

It is clear, in any case, that the jets interact strongly with molecular gas. The outflows are observed to be clumpier than normal cloud gas. Their speed also increases closer to the jet axis. Terrestrial jets create not only a sequence of shocks but also a collar of turbulent gas that widens until the central jet terminates. An analogous process could be occurring near young stars. Here, turbulence might be induced by jet material spewing out transversely from each shock. Indeed, careful observation of Herbig-Haro shocks does show material ejected in this manner, with the hot spray of ionized gas creating a cocoon surrounding the shock. This spray could also be responsible for stirring up the surrounding cloud gas and dragging it forward as a molecular outflow.

However, interstellar jets can extend far beyond the turbulent, clumpy outflow. Astronomers have detected a number of stellar jets extending over a parsec from the central star, with little or no molecular gas. These long chains of Herbig-Haro objects are gently curved, reflecting the rotation or perhaps precession of the underlying jet source. The period of rotation is of order 10,000 years. Despite the fact that they are traveling through nearly empty space, the shocks are slowing down. It is possible that momentum is being continually deposited in the lateral spray of gas. Indeed, small clumps of gas are sometimes observed off to the side of the main jet flow.

While much of the underlying physics is still murky, the phenomenon of bipolar flows has clear importance in the process of star formation. First, solar-type stars form inside relatively small molecular clouds called dense cores. Since only about a third of the core mass winds up in the star, the rest must somehow be dispersed. Winds are the obvious candidate. On a larger scale, stars are born not as isolated objects but in groups. Initially, these clusters are embedded within large molecular clouds. Many such primitive groups have been detected by infrared telescopes. When the group first appears in optical light, the stars are a few million years old, and there is still a substantial amount of ambient molecular gas. Again, these so-called T associations are commonly observed. On the other hand, we never see such groups with ages as high as ten million years. The reason must be that the stars themselves have driven off the molecular cloud and then dispersed into the field population. The obvious driving mechanism is ► [stellar winds](#). In this view, molecular outflows represent the dispersal of cloud gas, the key step in terminating star formation on both large and small scales.

Birthline

Steven W. Stahler
Department of Astronomy, University of California, Berkeley, CA, USA

Keywords

Stellar evolution · Star formation

Definition

After they have acquired most of their mass, but before they begin to fuse hydrogen, stars slowly contract. In the HR diagram, these ► [pre-main-sequence stars](#) descend along paths whose location depends on the stellar mass. All paths start at the birthline, a curve lying above and roughly parallel to the main sequence. When the stars within young clusters are placed in the HR diagram, they lie between the birthline and the main sequence. The two curves intersect at a mass of about ten solar masses. Stars of greater mass ignite hydrogen while they are still ► [protostars](#). If a young cluster contains such objects, they lie on the main sequence.

Overview

Astronomers view the evolution of stars using the Hertzsprung-Russell (HR) diagram. Within this plot of stellar luminosity versus surface temperature, the point representing a star

moves about as the object evolves. Mature stars that are fusing hydrogen lie along the so-called main sequence. Pre-main-sequence stars are situated higher in the diagram and gradually descend to the main sequence. The actual path of descent, known as the pre-main-sequence track, depends on the stellar mass. All pre-main-sequence tracks begin on another curve known as the birthline.

This description of the birthline is essentially theoretical. Observationally, young ► [stellar clusters](#) are studied by placing their members in the HR diagram (also called the color-magnitude diagram in this context). The birthline is the upper envelope of the stellar distribution. That is, the member stars lie in the region below the birthline and above the main sequence. In the very youngest clusters, most stars are crowded close to the birthline. In older groups, stars of lower mass lie further below the envelope, while more massive objects are already on the main sequence.

To see why there is a birthline, one needs to consider stellar evolution prior to the pre-main-sequence phase. The very youngest stars, known as protostars, are optically invisible and still acquire their masses from the surrounding clouds. As a protostar's mass increases, so does its radius. Indeed, the radius of the protostar can be predicted with fair accuracy from knowledge of its mass alone. Once cloud infall ceases, the star appears as a visible object on the appropriate pre-main-sequence track. The protostar mass-radius relationship dictates the initial positions of stars on their tracks. The locus of initial positions for various stellar masses defines a curve in the HR diagram that is the birthline.

An interesting feature of the birthline is that it intersects the main sequence. Specifically, the two curves join at about ten solar masses. More massive objects have no pre-main-sequence phase, but ignite hydrogen while they are still protostars. Thus, the early evolution of massive stars is quite different from that of the more common objects akin to the Sun. The intersection of the birthline and main sequence can be seen clearly in the HR diagram of the Orion Nebula

Cluster, the nearest region currently forming massive stars.

Bitumen

Emmanuelle J. Javaux
Palaeobiogeology-Palaeobotany-
Palaeopalynology, Geology Department,
Université de Liège, Liège, Belgium

Definition

Bitumen is the fraction of fossil organic matter in sedimentary rocks that is soluble in organic solvents (such as dichloromethane, hexanes, and methanol). It is a brown to black, highly viscous material that includes diverse organic macromolecules and chemical biomarkers. Bitumen is a component in petroleum.

Black hole mass · Accretion · Active galactic nuclei · Galaxies

Acronyms

M_{BH}	Black hole mass
SMBH	Supermassive black hole
IMBH	Intermediate-mass black hole

Definition

Black holes are defined as a region in spacetime where gravity is so strong that particles and electromagnetic radiation cannot escape. At the center of a black hole, density and gravity become infinite, in what is called the singularity. The boundary region within nothing can escape is called the event horizon. The radius of this event horizon, which determines the size of a black hole, is called Schwarzschild radius and is directly proportional to the black hole mass (M_{BH}): $R_{\text{Sch}} = 2GM_{\text{BH}}/c^2$ where G is the gravitational constant and c the speed of light (see Fig. 1). Mass, spin, and charge are the three properties that characterize black holes. A nonrotating black hole with no charge is called Schwarzschild black hole, while a rotating one is called Kerr black hole (see section “History”). At a distance of 1.5 times the Schwarzschild radius of a nonrotating black hole, there is a spherical boundary where photons moving on tangential trajectories to that sphere are trapped around the black hole in circular orbits. For a Kerr black hole, this photon sphere has a radius that depends on the spin of the black hole and the orbit of the photon.

Black Holes, Fig. 1 Anatomy of a Schwarzschild black hole. The event horizon is spherical and its radius is called Schwarzschild radius (R_{Sch}). At $1.5R_{\text{Sch}}$, there is the photon sphere inside which photons move around the black hole in circular orbits

History

Black holes were proposed by Karl Schwarzschild in 1916 to solve the Einstein equations of general relativity. Schwarzschild's metric described a nonrotating black hole with no charge (Schwarzschild black hole). The solution for a rotating black hole was found in 1963 by Roy Kerr (Kerr black hole), and that of a rotating black hole electrically charged by Ezra Newman in 1965. Several observational techniques have since then provided evidence for the existence of black holes (e.g., the detection of signatures of black hole accretion, measurements of stellar and gas kinematics within the radius of influence of a black hole; see section “[Basic Methodology](#)”). However, it was not until 2016 that the detection of gravitational waves provided direct evidence that black holes exist and merge (Abbott et al. 2016).

Overview

According to their mass, black holes are classified into three types:

- **Stellar-mass black holes.** They have a mass in the range $3 M_{\odot} < M_{\text{BH}} \leq 100 M_{\odot}$ and form when a massive star ($>15 M_{\odot}$) burns out its fuel supply and its internal pressure is no longer able to support gravitational collapse. Most stellar-mass black holes have been detected thanks to being part of an X-ray binary system in which the black hole accretes matter from a stellar companion via an accretion disk. The detection of X-ray and optical emission from X-ray binaries in the 1970s and 1980s (e.g., Cygnus X-1, LMC-X3; see review by, e.g., Remillard and McClintock 2006) provided the first observational evidence for the existence of stellar-mass black holes with a mass above $3 M_{\odot}$ (i.e., too large for a white dwarf or a neutron star). Since then, more than 20 stellar-mass black holes have been confirmed in X-ray binaries (e.g., Casares and Jonker 2014). The advent of gravitational wave interferometers such as LIGO and Virgo has provided the detection of tens of additional stellar-mass black holes (see Fig. 2).
- **Supermassive black holes (SMBHs).** They have a mass $M_{\text{BH}} \geq 10^6 M_{\odot}$ and reside typically at the center of massive galaxies (stellar mass $M_{*} \geq 10^{10} M_{\odot}$). SMBHs of up to $\sim 10^9 M_{\odot}$ in the local Universe are thought to result from the growth through cosmic time of stellar-mass black holes of a few tens of solar masses via accretion and mergers with other black holes. The detection of SMBHs of up to $\sim 10^{10} M_{\odot}$ when the Universe was less than 1 Gyr old (redshift $z \sim 7$; e.g., Wang et al. 2021) suggests they have to grow instead from higher-mass seed black holes of $100 M_{\odot} < M_{\text{BH}} < 10^6 M_{\odot}$ at $z > 10$ in order to reach $10^{10} M_{\odot}$ in such a short time (see Fig. 3). The best observational evidence for the existence of SMBHs comes from the measurement of stellar motions around the Galactic center, which revealed the presence of a SMBH of $4 \times 10^6 M_{\odot}$ (Ghez et al. 2008; Gillessen et al. 2009). More recently, the Event Horizon Telescope collaboration provided the first event-horizon-scale image of (the shadow of) a SMBH in the massive elliptical galaxy M87 (The EHT Collaboration

Black Holes, Fig. 2 Masses of all the compact binaries detected by LIGO/Virgo until October 2020. Stellar-mass black holes are shown in blue, neutron stars in orange. Those stellar-mass black holes and neutron stars detected

from electromagnetic observations (e.g., X-rays) are shown in purple and yellow, respectively. (Credits: LIGO/Virgo/Northwestern Univ./Frank Elavsky)

Black Holes, Fig. 3 Formation scenarios for IMBHs. Seed black holes in the early Universe could form from Population III stars, from mergers in dense stellar clusters formed out either from the second generation of stars or from inflows in protogalaxies, or from direct collapse of dense gas in protogalaxies, and grow via accretion and

merging to $10^9 M_{\odot}$ by redshift $z \sim 7$. SMBHs could also directly form by mergers of protogalaxies at $z \sim 6$. Those seed black holes that did not grow into SMBHs can be found in the local Universe as leftover IMBHs. (Credit: Mezcua (2017), International Journal of Modern Physics D, 26, 11, reproduced with permission)

et al. 2019). A SMBH that is actively accreting matter from its surrounding is called an Active Galactic Nucleus (AGN). An AGN can radiate over a trillion times the energy of the Sun, outshining the galaxy in which it resides.

- **Intermediate-mass black holes (IMBHs).** They have a mass $100 M_{\odot} < M_{\text{BH}} < 10^6 M_{\odot}$ and are thought to be the seeds from which SMBHs in the early Universe grew (see reviews by Mezcua 2017; Greene et al. 2020). Such seed IMBHs could form at $z > 10$ from the death of Population III stars of more than $260 M_{\odot}$, from direct collapse of pristine gas, or from runaway mergers in dense stellar clusters, among other possibilities (Rees 1978). They could then rapidly grow via accretion and mergers to become the SMBHs observed by $z \sim 7$ (see Fig. 3; Mezcua 2017 and references therein). Those seed black holes that did not grow should be found in the local Universe as leftover IMBHs, with a mass of $\sim 10^2$ – $10^3 M_{\odot}$ if they originated from Population III stars, of up to $10^4 M_{\odot}$ if they originated in nuclear stellar clusters, or of $\sim 10^4$ – $10^6 M_{\odot}$ if they formed via direct collapse of pregalactic gas. Hundreds of IMBH candidates have been found in the local Universe (e.g., Reines et al. 2013; Chilingarian et al. 2018; Mezcua and Domínguez 2020) and out to $z \sim 3.4$ (Mezcua et al. 2016, 2018b, 2019) as low-mass ($M_{\text{BH}} < 10^6 M_{\odot}$) AGN in dwarf galaxies. Because of their low mass (stellar mass $M_* \leq 3 \times 10^9 M_{\odot}$) and quiet merger history, dwarf galaxies are thought to resemble the first galaxies of the early Universe. Tens of additional candidates have been also found in globular clusters (e.g., Lützgendorf et al. 2013; see Table 1 in Mezcua 2017 and references therein) and in the outskirts of massive galaxies that have recently undergone a merger with a dwarf galaxy (e.g., Mezcua et al. 2015, 2018c; Barrows et al. 2019). The best observational evidence for the existence of IMBHs was provided by the LIGO/Virgo detection of a local IMBH of $142 M_{\odot}$ (Fig. 2; Abbott et al. 2020).

A possible fourth type of black holes are primordial black holes. These could have formed in

the presence of high-density fluctuations in the inflationary Universe or of abrupt changes in the plasma pressure, and could have masses ranging from sub-solar values to $10^8 M_{\odot}$ (e.g., Rubin et al. 2001; Carr and Kühnel 2020; Volonteri et al. 2021). Primordial black holes are currently being considered as a form of dark matter and for interpretation of gravitational wave events and, if sufficiently large, they can also be regarded as pregalactic seeds of SMBHs (e.g., Rubin et al. 2001; García-Bellido 2019; Carr and Kühnel 2020).

Basic Methodology

There are several ways to weight and detect black holes.

Dynamical Mass Measurements

In the case of stellar-mass black holes, most black hole masses come from dynamical measurements based on the detection of the radial velocity curve of the donor star in X-ray binaries (see review by, e.g., Casares and Jonker 2014). Other (indirect) methods, used to estimate the mass of a few IMBH candidates, include the detection of quasi-periodic oscillations (QPOs) and applying an inverse scaling relation found for stellar-mass black holes between QPO frequency and black hole mass (e.g., Pasham et al. 2014).

In globular clusters, the black hole mass of several IMBH candidates has been derived based on stellar kinematics and surface brightness profiles combined with dynamical modeling (e.g., Gebhardt et al. 2005; Lützgendorf et al. 2013). However, the absence of any signatures of accretion in the form of X-ray or radio emission precludes confirming the presence of IMBHs in these sources (e.g., Wrobel and Nyland 2020).

In the case of SMBHs, the best black hole mass measurements come from the monitoring of stellar proper motions around the black hole (e.g., Ghez et al. 2008; Gillessen et al. 2009) and from dynamical modeling of stellar and gas kinematics within the black hole sphere of influence (see review by, e.g., Kormendy and Ho 2013). Such dynamical mass measurements have been also

possible for a few nearby IMBHs (e.g., Davis et al. 2020). Beyond the local Universe (the Local Group in the case of IMBHs), where spatial resolution prevents performing such dynamical mass measurements, the detection of IMBHs and SMBHs has to rely on the finding of signatures of accretion in the form of AGN.

Active Galactic Nuclei (AGN)

AGN can be identified across the electromagnetic spectrum. In the optical and infrared regime, the presence of AGN ionization can be distinguished from ionization by galactic star formation using emission line diagnostic diagrams. AGN can also be identified by the detection of broad emission lines coming from gas clouds moving at velocities of ~ 3000 km/s around the central SMBH (the so-called “broad line region”). In the case of low-mass AGN in dwarf galaxies, these velocities can be of just hundreds of km/s (e.g., Reines et al. 2013). Such low velocities can be mimicked by some varieties of supernovae; however, unlike AGN, the broad line emission in supernovae would significantly decrease or disappear over a timespan of 5–15 years (e.g., Baldassare et al. 2016). In AGN with broad emission lines, the flux and width of the line can be used to estimate the black hole mass under the assumption that the gas in the broad line region is virialized.

In the mid-infrared regime, color-color diagrams can be also used to identify AGN (e.g., Stern et al. 2012). These diagrams are based on the colors that dust presents when heated by different mechanisms such as AGN or stars.

The detection of hard (2–10 keV band) X-ray emission from the corona of electrons sitting above the accretion disk around a black hole is a very strong tracer of black hole accretion. In massive galaxies, AGN can be identified as having an X-ray luminosity typically above 10^{42} erg/s. In dwarf galaxies, the AGN X-ray luminosity can be as low as 10^{38-39} erg/s, probing very low rates of accretion (e.g., Gallo et al. 2010). In this case, the contribution from X-ray binaries to the X-ray emission must be removed in order to confirm the presence of AGN (e.g., Mezcua et al. 2016, 2018b).

Some AGN eject a pair of collimated jets of relativistic plasma that radiate across the

electromagnetic spectrum via synchrotron emission. These jets are best observed at radio wavelengths, and their detection is a common tracer of AGN activity. Radio luminosities at 1.4 GHz above 10^{24} W/Hz are typically used to identify AGN, as these high radio luminosities cannot be explained even by extreme star formation. In the case of dwarf star-forming galaxies, the radio contribution from star formation processes must be removed in order to infer the presence of AGN (e.g., Mezcua et al. 2019).

Gravitational Waves

Gravitational waves are ripples in the space-time that propagate at the speed of light. They are generated by massive accelerated objects such as two merging black holes. In a black hole binary, gravitational waves are emitted during the inspiral phase, the merger, and the final ring-down. This was the case of the first detection of gravitational waves by the LIGO and Virgo interferometers in 2015, when two black holes of 29 and 36 $M_{\odot}$ merged into a new black hole of 62 $M_{\odot}$ (Abbott et al. 2016). Since then, tens of gravitational wave observations resulting from the merger of two stellar-mass black holes have been reported (Fig. 1). One of such black hole binaries resulted in a final black hole of 142 $M_{\odot}$, thus in the IMBH regime (Abbott et al. 2020). The detection of gravitational waves from SMBH binaries will have to await the next generation of space-based interferometers (e.g., Amaro-Seoane 2018).

Key Research Findings

Universality of Black Hole Accretion

The process of black hole accretion and its connection with the ejection of large-scale outflows (i.e., jets) is predicted to be a universal mechanism covering the whole black holes mass scale. This implies that the same disc-jet connection governing stellar-mass black hole does also take place in SMBHs (e.g., Falcke et al. 2004). Observational evidence for this universality of black hole accretion comes from the finding of a correlation between X-ray luminosity (proxy of accretion flow), radio luminosity (proxy of jet

Black Holes, Fig. 4 Fundamental Plane of Black Hole Accretion correlating radio luminosity, X-ray luminosity, and black hole mass. The solid line shows the best-fit

regression from Merloni et al. (2003). Galactic black holes (XRBs) are shown as red squares, Sgr A* as a yellow star, and AGN as green dots

emission), and black hole mass extending from stellar-mass to SMBHs (the so-called Fundamental Plane of Black Hole Accretion; see Fig. 4; e.g., Merloni et al. 2003; Plotkin et al. 2012). The Fundamental Plane of Black Hole Accretion can be used to estimate black hole masses when nuclear radio and X-ray luminosities are available (e.g., Mezcua et al. 2015, 2018c; Gültekin et al. 2019).

Black Hole-Galaxy Coevolution

Another key finding in black hole studies is that of a correlation between the mass of SMBHs and some host galaxy properties, such as bulge luminosity, stellar mass, or stellar velocity dispersion (see review by, e.g., Kormendy and Ho 2013), which implies that SMBHs and their host galaxies coevolve (see Fig. 5). While this synchronized black hole-galaxy growth was originally found for SMBHs of $>10^6 M_{\odot}$, recent studies have extended these correlations to the IMBH regime, where a flattening or large scatter seems to be observed (e.g., Martín-Navarro and Mezcua 2018; Baldassare et al. 2020; Greene et al.

2020). Feedback from the AGN onto the host galaxy is thought to be the main mechanism behind such black hole-galaxy evolution, via winds or jets that impact the formation of stars in the host galaxy and thus regulate its growth. Observational evidence for AGN feedback in massive galaxies comes from the finding that the radio jets of SMBHs fill the large-scale X-ray cavities of some galaxy clusters (e.g., McNamara et al. 2000). The effects of AGN feedback in dwarf galaxies are not so clear, but recent simulations (e.g., Sharma et al. 2020 and references therein) and observations (e.g., Mezcua et al. 2019; Liu et al. 2020) indicate it could be as significant as in massive galaxies.

Future Directions

The next generation of observational facilities will provide a major step forward in our understanding of black hole formation and evolution and the physics behind black hole accretion. Future radio observatories such as the Square Kilometer Array

Black Holes, Fig. 5 Black hole mass (M_{BH}) versus stellar velocity dispersion (σ_*). Gray squares are from the compilation of Kormendy and Ho (2013); dark gray squares show galaxies with classical bulges and light gray squares show galaxies with pseudo-bulges. Light blue circles show data for low-mass AGN from Xiao et al. (2011). Active dwarf galaxies with stellar velocity dispersion measurements measured in Baldassare et al. (2020) are shown as

red circles; active dwarf galaxies with previously existing data are shown in orange. Dwarf galaxies with dynamical black hole mass estimates are shown as dark blue squares. Also shown are the fits to the $M_{\text{BH}} - \sigma_*$ from Xiao et al. (2011; dashed line) and Kormendy & Ho (2013; solid line). (Credit: Figure and caption adapted from Baldassare et al. 2020, ApJ Letters, 898, L3, reproduced with permission)

(SKA) and X-ray satellites such as *Athena* or the mission-concept *Lynx* will provide a complete coverage of the phases that stellar-mass black hole transients undergo (i.e., the disk-jet coupling mechanism) and be able to detect SMBHs and their seed IMBHs out to $z = 10$ (e.g., Yu et al. 2015; Mezcua et al. 2018a; Whalen et al. 2020). In the new era of gravitational-wave astronomy, the Einstein Telescope will capture the gravitational-wave signal from millions of coalescing stellar binary black holes detectable out to $z \sim 15$ and up to masses of $10^3 M_\odot$ characteristic of (growing) black hole seeds, while LISA will detect the gravitational-wave signal from massive binary black hole coalescences ($\sim 10^4 M_\odot$ to $\sim 10^7 M_\odot$) across all cosmic ages (e.g., Amaro-Seoane 2018). A future of exciting discoveries awaits us.

Black Smoker

Yves Fouquet

Institut Français de Recherche pour l'Exploitation de la mer (IFREMER), Issy-les-Moulineaux, France

Definition

A black smoker is a sulfide-rich hydrothermal vent or hot spring on the ocean floor.

Hydrothermal aqueous fluids with temperatures up to 400 °C are issued from the vent. These fluids contain high concentrations of dissolved metals, sulfur species, and silica. Cooling and dilution as the fluid mixes with seawater causes the precipitation of Fe-Cu-Zn-Pb sulfides, which give rise to the dark color of the fluid (hence the name black smoker). Accumulation of sulfides around the vent builds up chimneys that may reach 60 m in height and support an exotic ecosystem of anaerobic fauna and ► [chemolithoautotroph](#) communities. Long-lived black smoker complexes may accumulate large volumes of sulfide which, when accreted to the continent, can be mined as ore deposits. Black smokers occur along modern ► [mid-ocean ridges](#), in back-arc basins and on the flanks of island arcs; their fossilized equivalents are found in Phanerozoic and Precambrian greenstone belts. The hydrothermal fluids form as seawater seeps down into the oceanic crust where it is heated and interacts with mainly basaltic rocks. The heated fluid then ascends through fractures and exits at the sea floor.

[Submarine hot spring](#)

Definition

A specific organic chemistry proceeds in the vicinity of a black smoker, or a hydrothermal vent, from which a cloud of black particles is emitted on the floor of the ocean. The main ingredients of the black particles are metal sulfides. Pyrite deposited around the smoker can serve as an efficient reducing agent for synthesizing reduced carbon compounds from primary carbon sources, such as carbon monoxide.

Overview

A black smoker is a type of hydrothermal vent found on the seafloor, appearing in the form of a chimney-like structure. Hydrothermal vents are located around fissures at mid-ocean ridges where tectonic plates are moving apart, from which heated water issues. Besides Earth, planetary bodies that might possibly have or had such hydrothermal systems include Europa, a satellite of Jupiter, and ancient Mars.

The cloud of black materials emitted out of the chimney includes a significant amount of black particles made of metal sulfides. When the hot water from the chimney comes in contact with the surrounding cold water, the black materials precipitate on top of the chimney, and it can gradually grow in height until its inevitable collapse. The piling up of the black chimney-like structures is considered to be a major source of sulfide ore deposits on Earth.

► **Pyrite** is a typical metal sulfide deposited by black smokers. It is a crystalline mineral composed of iron and sulfur. Pyrite possesses a positive surface charge at ambient seawater pH and accordingly can adsorb anions or organic compounds having anionic carboxylate or phosphate groups. In particular, when hydrogen sulfide reacts with iron in solution to form iron sulfide under conditions expected in the vicinity of the black smokers, the reaction produces electrons that can reduce various chemicals if relevant reactants are available. Iron sulfide formed in the hydrothermal environment can serve as a reducing agent that can drive a series of various

synthetic reactions. An experimental demonstration of the reducing capability associated with the formation of pyrite from hydrogen sulfide and iron is the synthesis of acetate from carbon monoxide (Huber and Wächtershäuser 1997).

It might therefore be expected that ► **Fischer-Tropsch**-type reactions using acetic acid or formic acid as the primary carbon sources may synthesize saturated fatty acids in the vicinity of hydrothermal vents, perhaps using cobalt-based catalysts where deleterious influences from sulfur catalyst poisoning could be avoided. Organic chemistry proceeding in and around black smokers could be quite rich, although some of the synthetic reactions might mutually be inhibitive. To date, the only unambiguously abiogenic organic compounds detected in these systems on Earth are simple hydrocarbons such as methane, ethane, and propane.

Definition

A blackbody is a hypothetical object that is a perfect radiator, absorbing all radiation that impinges upon it and emitting over the whole electromagnetic spectrum, however preferentially around a certain wavelength. The overall power and the spectral energy distribution depend only upon the object's temperature.

Overview

At the laboratory, a good approximation of a blackbody is a small-hole entrance to a cavity with absorbing walls within a block maintained at a fixed temperature. The spectral distribution of the blackbody emission is described by Planck's law and depends only on the temperature of the object: it peaks at a wavelength given by Wien's law, approximately $\lambda(\mu\text{m}) = 3,000/T(\text{K})$. On the short-wavelength side, the intensity decreases very fast, while it varies in a smoother way at wavelengths beyond the maximum (Fig. 1). The total power radiated by a blackbody is proportional to the fourth power of the temperature

(Stephan's law). As a first approximation, stars' and planets' emission can be described by blackbody radiation. The most perfect astrophysical blackbody is without any contest the Universe itself, which emits radiation peaking in the millimetric range, the cosmic microwave background (CMB); it fits Planck's law (at $T = 2.73 \text{ K}$) to within 1 part in 1,000, as revealed by the satellite COBE. The blackbody emission is indeed universal and is observed in a large variety of celestial objects at very different wavelengths. To give several examples, the emission of a star as the Sun, with $T = 6,000 \text{ K}$, peaks at $\lambda(\mu\text{m}) = 0.5 \mu\text{m}$ (visible); a planet as the Earth, with $T = 300 \text{ K}$, emits mainly at $\lambda(\mu\text{m}) = 10 \mu\text{m}$ (infrared); and the hot gas in a cluster of galaxies, with $T = 30 \times 10^6 \text{ K}$, peaks at $\lambda(\mu\text{m}) = 10^{-4} \mu\text{m}$, i.e., in the X-ray domain. Obviously celestial objects are not strictly black in general; this is why an approximation called the gray-body radiation is often used in models.

Bolometer

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Pyrometer](#); [Radiometer](#)

Definition

A bolometer is a detector that measures electromagnetic power incident on its absorbing surface by sensing a temperature change through some temperature-dependent physical mechanism in the detector, generally its electrical resistance. In a typical bolometer, the radiative power is thermalized either by a crystal lattice or by the electrons in the absorber. The small resulting temperature rise is sensed by a thermometer – a temperature-dependent semiconductor in the case of a semiconducting bolometer or a superconducting metal film in the case of a transition-edge superconducting detector. The lower the temperature, the better the performances of a bolometer: 100 mK is current in the most sensitive instruments.

Because they absorb any radiation, bolometers are able to measure the power received from celestial objects over a broad range of wavelength; they are however used mainly in the infra-red and millimeter bands.

Borate

Kateryna Klochko
Carnegie Institution of Washington, Washington,
DC, USA

Definition

Borate is a common oxoanion (BO_3^{3-}) found in boron-containing minerals (e.g., boracite, borax, kernite, colemanite, etc.), some borosilicates (e.g., tourmaline), and in association with natural carbonates. In natural aqueous environments, borates exist in equilibrium with boric acid $\text{B}(\text{OH})_3^\circ$ and borate anion $\text{B}(\text{OH})_4^-$. The pH-dependent equilibrium between these species in seawater ($\text{pK}_a = 8.597$, (Dickson 1990)) is accompanied by boron isotope fractionation of 27.2‰

(Klochko et al. 2006). The two naturally occurring and stable isotopes are ^{11}B (80.1%) and ^{10}B (19.9%). The mass difference results in a wide range of boron isotopic compositions in terrestrial environments, and boron isotopic compositions in marine carbonates have been used as a paleo-pH proxy of the oceans (Hemming and Hanson 1992). Borates have also been found to stabilize ► [ribose](#) (Ricardo et al. 2004), which may have been important for the origin of life on early Earth, although the prebiotic availability of borate minerals has been questioned (Hazen et al. 2008).

Nucleosynthesis · pH · Seawater

Definition

Boron has two stable isotopes (^{10}B and ^{11}B), ^{11}B being the most abundant since the average terrestrial $^{11}\text{B}/^{10}\text{B}$ isotope ratio is of ≈ 4.04 . Strong variations of this ratio were present in the presolar molecular cloud and in the accretion disk, part of them due to the radioactive decay of ^{10}Be to ^{10}B . Low-temperature isotopic fractionations are responsible of large (up to $\approx 100\%$, where ‰ is parts per mil) variations of the $^{11}\text{B}/^{10}\text{B}$ ratio in seawater and terrestrial rocks. Some of these variations may be used to reconstruct paleo-seawater pH and paleo-atmospheric P_{CO_2} .

Overview

Boron is one member of the lithium-beryllium-boron (Li-Be-B elements) clan, three elements which share some unique properties due to a common nucleosynthetic history. The cosmic abundance (or solar abundance) of Li-Be-B elements (Lodders 2003) is a factor of $\approx 10^7 - 10^{10}$ lower than elements of neighboring atomic mass such as He, C, and O. This is due to the fact that light elements (D and Li-Be-B clan) cannot be synthesized by nuclear reactions in stellar interiors at temperatures higher than $\approx 10^6$ K, being rather destroyed at these temperatures (Burbidge et al. 1957). Contrary to ^7Li , for which a fraction is produced during the Big-Bang nucleosynthesis, the two stable isotopes of B (^{10}B and ^{11}B) are produced in the interstellar medium by endothermic spallation reactions. These reactions occur at high energies, typically higher than a few MeV (Reeves et al. 1970). High-energy collisions between accelerated protons (and alpha particles) and O and C nuclei at rest (mostly ^{16}O and ^{12}C) are responsible of the production of ^{10}B and ^{11}B with an isotope ratio $^{11}\text{B}/^{10}\text{B} \approx 2.5$, as modeled from available cross sections (Meneguzzi et al. 1971) and as measured in present-day galactic cosmic rays (GCR) ($^{11}\text{B}/^{10}\text{B}$ from ≈ 1.5 to ≈ 3.2 depending on the energy, Krombel and Wiedenbeck 1988). The poor efficiency of these reactions is responsible of the low cosmic abundance of B.

This nucleosynthetic origin makes the isotopic composition of B in the Solar system quite intriguing. In the Earth and meteorites, the $^{11}\text{B}/^{10}\text{B}$ ratio (≈ 4.04 ; Palmer and Swihart 1996) is enriched in ^{11}B relative to GCR. Boron in diffuse interstellar clouds is also ^{11}B -rich ($^{11}\text{B}/^{10}\text{B} = 3.4 \pm 0.7$, Lambert et al. 1998) relative to GCR. This ^{11}B enrichment has been proposed to result from the addition of B made by low-energy spallation which would be enriched in ^{11}B according to predictions made from available cross sections (Reeves 1994) and/or to the addition of B made by neutrino-induced spallation of C in type II supernovae (Lambert et al. 1998). These processes are likely to operate at galactic time scales but irradiation processes around the young forming Sun also produced a fraction of the Solar System boron. This is demonstrated (McKeegan et al. 2000) by the presence in Ca-Al-rich refractory inclusions ($\blacktriangleright$ CAIs) from chondritic meteorites of ^{10}B excesses due to the radioactive decay of short-lived ^{10}Be (^{10}Be β decays to ^{10}B with a half-life of 1.39 Ma). The magnitude of the ^{10}B excesses implies that the $^{10}\text{Be}/^9\text{Be}$ ratio at the time of formation of CAIs was up to $\approx 8.8 \times 10^{-4}$ (Chaussidon et al. 2006) but large variations are expected in this ratio depending on the conditions of the irradiation processes in the early Solar System (Chaussidon and Gounelle 2006). One attractive model is the formation of ^{10}Be and of B isotopes (^{10}B and ^{11}B) by reactions between flares emitted by the young active Sun when a classical T-Tauri star and grains and/or gas at the inner edge of the accretion disk.

While B isotopic variations inherited from nucleosynthesis might be present in the accretion disk (Chaussidon and Robert 1995, 1998), they are most probably averaged at planetary scale. However, B isotopic variations around this ratio of ≈ 4.04 are widespread in terrestrial rocks. They are due to low-temperature stable isotopic fractionations and are generally reported as deviations in permil from the $^{11}\text{B}/^{10}\text{B}$ ratio of the international standard (NBS boric acid SRM 951 with $^{11}\text{B}/^{10}\text{B} = 4.04367$, Catanzaro et al. 1970) using the classical delta notation ($\delta^{11}\text{B}_{\text{sample}} = ((^{11}\text{B}/^{10}\text{B})_{\text{sample}} / (^{11}\text{B}/^{10}\text{B})_{\text{SRM951}} - 1) \times 1000$). Boron in the silicate Earth is grossly distributed

as follows: $\approx 10\%$ in seawater, $\approx 35\%$ in the crust (continental and oceanic), and $\approx 55\%$ in the mantle (upper plus lower mantle). Very little is known for boron isotope variations in organic matter (Williams et al. 2001) because of analytical difficulties, even though boron is a key element for life and has a complex biogeochemical cycle (Park and Schlesinger 2002). Boron in the primitive mantle has a $\delta^{11}\text{B} \approx -10\%$ as indicated by oceanic basalt glasses (Chaussidon and Marty 1995) and this is most probably the bulk $\delta^{11}\text{B}$ of the Earth. There is no significant isotopic fractionation associated with the extraction of boron from the mantle to the crust, because boron isotopic fractionations at mantle temperatures are minimum. This is confirmed by analyses of tourmalines from granitic rocks of various ages which allow to define an average $\delta^{11}\text{B}$ for the continental crust (at a mean age of 2 Ga) between $\approx -8\%$ and $\approx -13\%$ (Chaussidon and Albarède 1992). However, in more details, mass balance implies that the $\delta^{11}\text{B}$ of the crust has evolved over geologic times in response to crustal growth and to the change of the relative fractions of B hosted in the main surface reservoirs. In fact, a major isotopic fractionation occurs for boron during adsorption processes on clay minerals (Schwartz et al. 1969; Palmer et al. 1987) and various other phases such as, for instance, humic acids (Lemarchand et al. 2005). This isotopic fractionation is due to the facts that (1) boron in solution occurs both as boric acid ($\text{B}(\text{OH})_3$, named B_3 in the following) and borate anion ($\text{B}(\text{OH})_4^-$, named B_4 in the following), the relative proportions of the two species depending on the acidity constant (pK) of boric acid, which itself depends on temperature and salinity, and (2) there is a strong equilibrium isotopic fractionation between boric acid and borate anion ($\alpha_{\text{B}_3-\text{B}_4} = 0.97352$ at 25 °C, Pagani et al. 2005; Klochko et al. 2006; Rollion-Bard and Erez 2010). Boron adsorbed at the surface of growing minerals (clays, carbonates) is dominantly B_4 , which is thus strongly isotopically fractionated from the solution. During crystal growth, this adsorbed boron is incorporated into the structure of the minerals (Spivack et al. 1987). This property allows the boron isotopic fractionation to be

calculated between a mineral and the pH of the solution and has been widely used and investigated to try to reconstruct paleovariations of seawater pH and atmospheric P_{CO_2} (e.g., Pearson and Palmer 2000, refs. therein). These reconstructions are complicated by the fact that the $\delta^{11}\text{B}$ of seawater might have changed over geological times (Lemarchand et al. 2000) and that a significant fraction of B_3 can also be adsorbed. However, boron isotopes are one of the best tools used to infer the pH of a solution from which a mineral grew. This has been useful to unravel the origin of the so-called vital effect on the oxygen isotopic fractionation between biogenic carbonates and seawater. Micrometer scale variations of $\delta^{11}\text{B}$ values in coral skeletons have shown that strong pH variations occurred during the formation of calcite and that these changes of pH modify the kinetic of oxygen isotopic exchanges between dissolved carbonate species (H_2CO_3 , HCO_3^- and CO_3^{2-}) and water via the two reactions of hydration and hydroxylation (Rollion-Bard et al. 2003). Boron isotopes in sedimentary rocks are thus key for the reconstruction of past paleo-environmental changes on Earth.

Definition

In chemistry and physics, the branching ratio is the ratio of the rate constant for a particular product of a reaction to the rate constant for the total set

of possible products. For example, in nuclear physics, the branching ratio for a decay process is the ratio of the number of particles which decay via a specific decay mode with respect to the total number of particles which decay via all decay modes. It is also equal to the ratio of the partial decay constant to the overall decay constant.

[Rubble rock](#)

Definition

Breccia is an Italian word that means “rubble.” Indeed, breccia is a detrital rock composed of angular fragments of minerals or rocks. These fragments can be produced by sedimentary, magmatic, or tectonic processes. Breccia containing angular clasts and fine-grained matrix produced by meteoritic impacts is a common rock covering planetary surfaces such as the Moon’s highlands.

Overview

A *sedimentary breccia* is a coarse-grained (particle size >2 mm) detrital rock composed of

angular rock or mineral fragments held together by a cement or dispersed in a fine-grained solidified matrix. It originates as a result of localized sedimentary processes such as talus accumulation (*sedimentary breccia*), disturbance during sedimentation (*intraclastic breccia*), or collapse of rocky surfaces such as the roof of a cave (*collapse breccia*). The reason that the rock debris is angular is indeed an indication that the rock was little exposed to weathering and that transport by meteoric agents (winds, water, ice) was minimal. *Glacial breccia* is the product of mechanical fragmentation of the rock substratum by a moving ice sheet or glacier. These products are often found in moraines which are accumulation of unconsolidated debris previously carried along by a glacier or an ice sheet.

Volcanic breccia results from explosive eruptions (*pyroclastic or tuff breccia*), hydrovolcanic (highly pressurized water) fragmentation in diatremes (funnel-shaped pipes), or mechanical fragmentation in intrusive settings.

Local tectonic processes such as brittle deformation along a fault can produce a *fault (or tectonic) breccia*. Sometimes this breccia can contain vitreous debris derived by frictional melting of the rocks along the fault plane during large earthquakes and are called *pseudotachylitic breccia*.

Heavily craterized planetary surfaces contain also breccia produced by meteorite impacts, such as on the Moon. On Earth, plate tectonics have shaped the planetary surface in the last 3 billion years wiping the remains of meteoritic breccias except in a few well-preserved large impact areas, such as the Vredefort (South Africa), or Sudbury (Canada) structures, or several smaller size craters. These breccia contain a complex mixture of target-rock lithologies. Impact breccias characterized by partial melting of the targeted rock are thus often called *pseudotachylitic breccia* or PTB (Reimold et al. 2017), for their similarities with frictional tectonic breccia. The most likely process for the genesis of PTB is decompression melting upon formation and collapse of the central uplift, during the modification stage of impact cratering.

On the Moon, there are two families of breccias: *lunar regolith breccias* and *fragmantal*

breccias. Regolith is the name of the layer of unconsolidated material that covers solid bedrock at the surface of a planet. On Earth is synonymous of “soil.” On the Moon, the *regolith* and *fragmented breccias* are both generated by the impact of a bolide on the planetary surface. However the first consists of fine-grained material, partially melted, from the upper few meters; the second consists of material that was deeper settled, likely fragmented rock that shattered on place by the impact-generated shock waves. The *lunar regolith breccias* consist of two distinct lithologies: *glass spherules* and *agglutinates*. Glass spherules can be produced either by rock melted during the impact and ejected in form of small globs that are rapidly quenched or by erupting volcanoes. Agglutinates are tens of micrometers to a few millimeters glassy breccias formed when a micrometeorite strikes the lunar regolith. Depending on the dominant mineralogy of the targeted rocks by the meteorite impact, lunar breccias are also named as *anorthositic breccias*, *feldspathic breccias*, or *highlands breccias*.

Finally, pieces of those breccias can be ejected from the planet during impacts and then brecciated meteorites can be found on Earth, as lunar achondrite NWA 2995 which is a fragmental breccia found in 2005 in Algeria. Martian meteorites can also be composed of breccias, and following the Meteoritical Society recommended classifications, a *Martian (basaltic) breccia* means “a Martian meteorite that is a breccia dominantly composed of basaltic clasts; this Martian meteorite is not assigned to the shergottite, nakhlite, or chassignite types.”

Bremsstrahlung Radiation

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Free-free emission](#)

Definition

Bremsstrahlung is a German word used in physics to describe the electromagnetic radiation emitted by a plasma in which high-speed charged particles (electrons, protons) are accelerated by other charged particles (ions). The bremsstrahlung radiation emitted by a plasma shares some analogy with ► [blackbody](#) radiation and is, as well, considered as *thermal emission*, as opposed to non-thermal processes, like synchrotron emission. The notable difference with blackbody emission is that bremsstrahlung features a plateau of quasi-constant intensity in a broad region of wavelengths, while the blackbody emission exhibits a pronounced peak.

Brown Dwarf

Gibor Basri¹ and Adam J. Burgasser²

¹Astronomy Department, University of California, Berkeley, CA, USA

²Center for Astrophysics and Space Sciences, Department of Physics, UC San Diego, La Jolla, CA, USA

Keywords

Very cool stars · Very low-mass stars

Synonyms

[Substellar objects](#)

Definition

A brown dwarf is a gravitationally bound astronomical object intermediate in mass between stars and giant planets, sometimes called a substellar object. Brown dwarfs are different from stars because they never achieve stable luminosities by nuclear fusion and are different from planets because they fuse light elements such as deuterium and lithium early in their evolution. Brown dwarfs are structurally supported by electron degeneracy pressure, and the lack of sustained fusion causes these objects to cool and dim over

time. A young brown dwarf closely resembles a very low-mass star in physical and spectral appearance, but as they cool, brown dwarfs develop atmospheres that are more like those of warm giant planets.

Overview

Brown dwarfs are classified by astronomers as substellar objects, meaning they have masses below that of hydrogen-fusing stars, about 75 Jupiter masses or 0.072 solar masses for a solar elemental composition. This is the mass above which the nuclear luminosity from the fusion of ordinary hydrogen in the core balances the thermal luminosity at the surface, resulting in an object that is in thermal equilibrium. Brown dwarfs are distinguished from planets because they have masses above the threshold for the fusion of deuterium (“heavy hydrogen,” a rare isotope produced in the Big Bang), about 14 Jupiter masses. Brown dwarfs are believed to form in a manner analogous to stars, contracting out of giant molecular clouds under the influence of self-gravity. In the hydrostatic stage of contraction, the cores of protostars and brown dwarfs increase in temperature, eventually initiating deuterium fusion. After deuterium is depleted in a few million years, true stars will continue to contract until their central temperatures are high enough to fuse ordinary hydrogen. For sun-like stars, the thermal pressure from this reaction provides the pressure support to stop a star’s collapse, and the nuclear luminosity eventually balances the surface luminosity, allowing a star to join the “main sequence.” While massive brown dwarfs can fuse light elements, such as deuterium, lithium, beryllium, and boron, and ordinary hydrogen early in their evolution, the luminosity from these reactions is insufficient to balance the thermal radiation at the surface over a long time period, resulting in an object that loses thermal energy by surface radiation.

Brown dwarfs never reach the temperatures necessary for sustained hydrogen fusion because their contraction is halted by free electron degeneracy pressure. This form of pressure does not

depend on temperature and is a consequence of the Paul exclusion principle that prevents electrons from occupying the same low-energy quantum states at very high densities. Degeneracy pressure scales with density, resulting in the counterintuitive property that adding more mass to a brown dwarf requires a higher-density core to support it, and hence produces a smaller object. Thus, a fully contracted brown dwarf is slightly smaller than Jupiter, with the most massive brown dwarfs being the smallest and densest hydrogen-rich objects known. Brown dwarfs achieve this state before reaching the temperatures necessary for sustained hydrogen fusion, and the imbalance between core fusion luminosity and surface thermal luminosity results in an endless slide toward cooler and fainter states (Chabrier and Baraffe 2000; Burrows et al. 2001). It is worth noting that the non-fusing remnant cores of stars like the Sun which have depleted their hydrogen supply are also supported by free electron degeneracy pressure. These remnants, known as “white dwarfs,” are both considerably hotter (hence “white”) and much more massive than brown dwarfs and can be as small as the Earth in radius, ten times smaller than a brown dwarf.

History

Brown dwarfs were first hypothesized in the early 1960s by Kumar (1962) in the United States and Hayashi and Nakano (1963) in Japan. Kumar originally called these objects “black dwarfs”; Jill Tarter proposed the name “brown dwarf” in 1975 to account for their evolving colors as they cool. Brown dwarfs are not actually brown. They would appear to the eye to range from deep red to magenta depending on their temperature, as the bulk of their radiation emerges at infrared wavelengths with only a small fraction emerging at visible wavelengths. Searches for brown dwarfs were conducted from the 1970s onward, and while some very cool stars and brown dwarf candidates were identified, no bona fide brown dwarfs were definitively known before 1994. A brown dwarf can be identified by having an effective temperature below the minimum main

sequence stellar temperature, about 1,800 K. Such objects, which may be identified as companions to other stars or found as free-floating objects, are extremely faint and red and eluded detection until the development of sensitive infrared cameras. Alternately, warmer and brighter young brown dwarfs can be distinguished from stars of the same temperature by the detection of lithium absorption in their spectrum (Magazzu et al. 1993). Lithium is destroyed in fusion reactions in the core that occur at a lower temperature than hydrogen fusion. Because the interiors of very low-mass stars and brown dwarfs are fully convective, lithium is mixed into the core so that fusion can deplete all of a star’s lithium content on time scales of 10–100 million years (this makes lithium depletion a useful mechanism for age-dating young clusters; see Stauffer et al. 1998). On the other hand, brown dwarfs with masses below 60 Jupiter masses never get hot enough to destroy lithium. In 1995, both methods produced verified discoveries (Basri 2000). The lithium test was used to confirm the brown dwarf status of two young objects in the Pleiades cluster, PPl 15 and Teide 1 (Rebolo et al. 1995, 1996; the first object was later determined to be the first brown dwarf binary). In the same time frame, astronomers at Palomar Observatory identified a faint companion to a very low-mass red dwarf star, Gliese 229, whose infrared spectrum indicated the presence of methane in its atmosphere, indicating an atmospheric temperature less than about 1,300 K (Nakajima et al. 1995; Oppenheimer et al. 1995). These three objects are widely recognized as the first brown dwarf discoveries and have been followed by the detection of thousands of brown dwarfs confirmed by their temperature, presence of lithium absorption, and in some cases direct mass measurements. The majority of brown dwarfs now known were uncovered by wide-field infrared imaging surveys such as DENIS, 2MASS, SDSS, and *WISE*.

Key Research Findings

The surface temperature of a brown dwarf depends on both its mass and age. All brown

dwarfs start off as large and relatively hot objects heated by their gravitational contraction, with the more massive brown dwarfs starting off hotter as they transform more gravitational potential energy to thermal energy. Brown dwarfs subsequently cool with time. As such, a younger, less massive brown dwarf can have the same temperature as an older, more massive one. This characteristic makes brown dwarfs fundamentally different from main sequence stars, for which temperature is directly related to mass and only weakly dependent on age. The most massive and youngest brown dwarfs have temperatures as high as 3,000 K, overlapping with the temperatures of red dwarf stars. All brown dwarfs eventually cool below the minimum stellar temperature of about 1,800 K, with more massive brown dwarfs taking more time to reach this threshold. A 25-Jupiter mass brown dwarf takes about 100 million years to reach this limit, while a 60-Jupiter mass brown dwarf takes about 1 billion years. The oldest and least massive brown dwarfs can cool to temperatures below 300 K. Since age and size are often hard to measure directly, the mass of a brown dwarf will be uncertain unless it is located within a cluster or bound to a more massive star of known age (where the mass is inferred from evolutionary models) or is part of a binary with a measured orbit (where the mass can be determined directly). Eclipsing binary brown dwarf systems, for which both size and mass can be independently measured, are exceptionally valuable systems for testing models for brown dwarfs. Several such systems are now known, most of which consist of a brown dwarf closely orbiting a main sequence star (Carmichael et al. 2020).

The youngest and warmest brown dwarfs have atmospheres and spectra that are largely identical to those of the least massive stars, known as M dwarfs. These spectra show strong absorption bands of metal oxides such as H_2O , CO, TiO, and VO. As brown dwarfs cool below about 2,200 K, mineral condensate grains form in their atmospheres, which are often characterized as “dusty” (Allard et al. 2001; Lodders and Fegley 2006). The dust is made of the most refractory compounds: calcium, aluminum, and titanium oxides like corundum (Al_2O_3) and perovskite (CaTiO_3).

The presence of dust smoothens and reddens the infrared spectra of brown dwarfs, while the fading TiO and VO absorption bands at optical wavelengths are replaced by metal hydrides (FeH, CrH, CaH) and heavily pressure-broadened features from the electronic transitions of neutral alkali elements, especially sodium and potassium (weaker lines from rubidium and cesium are also seen in these spectra). These spectral differences led to the delineation of a new stellar spectral class, the L dwarfs (Kirkpatrick et al. 1999). At even cooler temperatures, below about 1,300 K, carbon transitions from CO to CH_4 , resulting in broad methane features in the infrared which signify another new stellar spectral class, the T dwarfs (Burgasser et al. 2006). The transition from L dwarf to T dwarf is also reflected in a rapid depletion of condensates from the atmosphere, a process that is still not fully understood. At lower temperatures, nitrogen transitions from N_2 to NH_3 , which can be discerned in mid-infrared spectra, while new condensates composed of sulfides and halide salts emerge. The coldest and most recently defined spectral class, the Y dwarfs, encompasses these objects and extends in temperature from about 700 K to below 300 K, the temperature of the coldest brown dwarfs currently known (Cushing et al. 2011).

The condensate species that form in the L dwarfs and in the late T and Y dwarfs are believed to be organized into cloud structures, based on the balance of vertical upwelling, downward settling, and atmospheric dynamics. The structures of these clouds are inferred from the rotational modulation of their brightnesses and spectra (Biller 2017). Periodic brightness variations trace azimuthal cloud structure, while long-term changes may reflect jet and band structure analogous to the gas giant planets. Cloud vertical structure can be traced by brightness and phase variations at different wavelengths. The vast majority of brown dwarfs appear to be variable, with the strongest amplitudes found at the transition between the L dwarf and T dwarf classes. In addition to these time-dependent phenomena, variations in the spectral energy distributions of brown dwarfs of similar temperatures have been ascribed to differences in global cloud properties,

and the most successful atmosphere models of brown dwarfs incorporate variations in the cloud structure, composition, and fractional surface coverage (Saumon and Marley 2008). Some of this variance can be attributed to other properties, such as surface gravity (young L-type brown dwarfs appear to be “cloudier”), elemental composition (brown dwarfs with fewer heavy elements are less cloudy), or viewing angle. The additional opacity from condensate grain scattering can also influence the physical structure of a brown dwarf, with the increased opacity modulating radii by of order 10%. The actual formation processes of condensates, their size distribution and composition, and optical properties remain active areas of investigation; even the formation of clouds on the Earth is tricky.

It appears that brown dwarfs form in much the same way as stars, constituting the lowest-mass end of the star formation process (Luhman et al. 2007). This is evident from the continuous nature of the initial mass function across the hydrogen-fusing mass limit and the fact that newly formed brown dwarfs possess the same kinds of circumstellar disks and jets as newly formed stars. Brown dwarfs have lower accretion rates and smaller and longer-lived disks than stars but nevertheless undergo similar stages of pre-main sequence evolution. The existence of brown dwarf disks suggests that they may also harbor planetary systems. The lowest-mass star with a confirmed planetary system, TRAPPIST-1, has a mass just above the hydrogen-fusing limit (Gillon et al. 2017). Brown dwarfs are found as isolated objects and as companions to stars and even to each other. The binary fraction of brown dwarfs (10–25%) is lower than that of very low-mass stars (20–35%), in line with the known decrease of the binary fraction with stellar mass along the main sequence (Duchêne and Kraus 2013). Brown dwarf binaries are also more closely separated and found in more equal-mass compositions than stars. Because brown dwarf masses are below the typical Jean’s mass limit of giant molecular clouds, alternative formation scenarios have been proposed for these objects. These include formation in especially turbulent environments, early ejection from clusters of protostellar clumps, photoevaporation in

the proximity of a massive star, and fragmentation of massive protostellar disks (Whitworth 2018). While the collection of observational evidence to distinguish these various formation paths is ongoing, the demographics of young and evolved brown dwarfs is consistent with a population of isolated objects forming like stars down to the high planetary mass domain. These results apply for young clusters and the population of stars and brown dwarfs closest to the Sun. Little is as yet known about the frequency of brown dwarfs in other galactic populations (the halo and bulge), globular clusters, or extragalactic populations.

One respect in which brown dwarfs are more like giant planets than stars is that they tend to be very rapid rotators, with periods as short as a few hours rather than days to months for most low-mass stars. This behavior reflects a change in angular momentum loss mechanisms, which for stars like the Sun is driven by magnetized winds and leads to a steady decline in rotation rates (and magnetic activity) with time. Brown dwarfs are magnetically active, as evidenced from persistent nonthermal emission, in particular radio emission, and Zeeman splitting of metal line and band features even among the coldest brown dwarfs. It is likely that as a brown dwarf surface cools, its magnetic field becomes decoupled from its increasingly neutral photospheric plasma, making it difficult to sustain the coronal heating that drives winds (Reiners and Basri 2008). The properties of magnetic fields on brown dwarfs may also differ from those of low-mass stars, being produced in a fully convective interior subject to rapid rotation. The magnetic radio emission is also distinct, being far brighter than expected from scaling laws linking X-ray heating and radio emission in stars and exhibiting unique phenomena such as highly polarized pulsations and both short- and long-term variability. Nonthermal emission from brown dwarfs may be more similar to the auroral emission processes on the Solar planets, another shared trait.

Infrared sky surveys and other techniques have uncovered thousands of brown dwarfs in nearly every environment in the Milky Way Galaxy. The demographics of brown dwarfs in young clusters and the local field populations suggest that the

ratio of brown dwarfs to stars is roughly 1:6, which implies there are tens of billions of brown dwarfs in our Galaxy. Before their discovery, brown dwarfs were conjectured to be a significant component of “dark matter” since they are too faint to be seen except when very close by, but both microlensing experiments and the now-established luminosity function of brown dwarfs have firmly ruled this out. Nevertheless, brown dwarfs are an important probe of the Milky Way system. Because brown dwarfs do not fuse hydrogen, they never “die,” which means that every brown dwarf ever formed still exists and has preserved its birth composition of elements, with the exception of deuterium and (in the most massive brown dwarfs) lithium, beryllium, and boron. Since they cool with time, brown dwarfs also provide age information useful for tracking the Milky Way’s star formation history. Finally, as brown dwarfs cool, their atmospheres increasingly take on the characteristics of “hot” giant planets, valuable for exoplanet studies.

History

Giordano Bruno (1548–1600) was an Italian heterodox philosopher and theologian. Because of his ideas and writings, Giordano Bruno left Naples, his home town, in 1576. In 1583, he abandoned his life as a Dominican friar and left Italy, living thereafter in France, England, and Germany.

As a supporter of Copernicus's heliocentric theory, of which he became a staunch supporter, Giordano Bruno collected countless enemies because of his unorthodox ideas. In his book *De l'Infinito, Universo e Mondi* (1584), he argued that the universe was infinite, that it contained an infinite number of worlds, and that these are all inhabited by intelligent beings. He came to Venice in 1591, where he got arrested and tried by the Inquisition in 1592. After he recanted, Bruno was sent to Rome the same year, for another trial. After eight years of successive interrogations, he was declared a heretic. In 1600, Bruno was burned at the inquisitorial stake because of his opinions concerning the Trinity, virginity of Mary, transubstantiation, and other beliefs contrary the Catholic faith.

History of earth · Spontaneous generation

History

Georges-Louis Leclerc, Comte de Buffon (1707–1788) was one of the most important French naturalists of the eighteenth century. In 1739, he became *Intendant du Jardin et du Cabinet d' Histoire Naturelle du Roi*. For four decades (1749–1789), he published his *Histoire Naturelle* (22 volumes, with the supplements).

From the beginning of this voluminous work, he presented several important concepts and used them in his description of living beings. According to him, every animal and vegetable organism was made of “organic molecules,” which were the smallest living entities. In each body, the organic molecules took the mark of the “internal mold” specific for each species. During reproduction, the male and the female would give some organic molecules with the mark of the parental internal molds, and the young organism would then depend on it.

It is very important to note that Buffon was not a transformist. Indeed, he conceived some modifications in the limit of each species, which could be reversible; however, he never accepted any link between species by means of modifications.

As far as the history of Earth is concerned, Buffon's conception evolved during his career. In the first volume of his *Histoire Naturelle*, he developed a cyclic conception of the history of Earth. Thirty years later, he claimed a sagittal theory and gave a description of “the Epochs of the Nature” in a supplementary volume (V) of his *Histoire Naturelle*. He described seven epochs. At the beginning, the Earth was an incandescent sphere of matter. The temperature progressively decreased and the Earth became solid. Therefore, his history of Earth was irreversible and depended on the decrease in temperature.

Buffon asserted that species were formed by spontaneous generation and had been constituted by the organic molecules that were very abundant in the soil during the first epochs of nature. For him, spontaneous generations were still active in nature, but only for the little species.

Definition

Bulk Silicate Earth refers to the original chemical composition of the silicate part of the Earth, after the separation of the metallic core but prior to the differentiation of the crust. For this reason, the

Bulk Silicate Earth composition is synonymous with the composition of the Earth's "primitive mantle."

Overview

The present-day "silicate" part of the Earth, that is, the mantle and the crust (both oceanic and continental), makes up 67.5% of the whole Earth's mass, while the metallic core makes up the remaining 32.5%. The silicate portion of the Earth is presently composed of several sub-reservoirs, namely the continental and oceanic crusts, the depleted mantle (i.e., depleted in meltable elements which were extracted by partial melting from the mantle to form the crust), and the primitive mantle, which is inversely enriched in meltable elements having not, *à priori*, participated to the formation of the crust. It would be reasonable to assume that the original BSE chemical element composition is the mass balance between these different silicate reservoirs. However, it is not a simple calculation because these reservoirs have heterogeneous chemical compositions (particularly the continental crust), the amount of crust recycled back in the mantle through eons by plate tectonics is unknown, as well as the exact size of the mantle sub-reservoirs.

There are fundamentally two approaches to establish the BSE initial composition of the Earth, both with their limitations (e.g., Lyubetskaya and Korenaga 2007). The first is called the petrological model and it is based on the chemical composition of the least differentiated peridotites (e.g., Jagoutz et al. 1979; Sun 1982). Peridotite is an Mg-rich rock made of olivine, pyroxene, and an aluminous mineral phase such as plagioclase, garnet, or spinel. The mantle would have basically a peridotitic composition. However, a large spectrum of peridotite compositions exists with "lherzolites" being the richest in elements, which are easily melted (Ca, K, Na, Al), and "harzburgites," which are depleted in those "meltable" elements. The degree of depletion in meltable elements indicates the progressive partial melting of peridotite to form basalts during oceanic crust extraction. Thus, the

average major-elements composition of the least depleted (i.e., the most primitive) peridotites would give an estimate of the BSE (Jagoutz et al. 1979). However, because of the large scattering in the major-element composition of worldwide peridotites and the fact that a significant amount of the present-day mantle has undergone partial melting to extract the Earth's crust, the resulting BSE composition remains somehow approximate. This is particularly true for high incompatible trace elements (such as U, Th, Cs, Ba), which are preferentially partitioned in the Earth's crust.

An alternative means of estimating the BSE is to look at the chemical composition of the most undifferentiated/primitive meteorites: the chondrites, which do not show any evidence of having been melted since the formation of their parent bodies at the beginning of the Solar system. Among them, the CI carbonaceous chondrites have been proposed to be the best candidates to represent the geochemical composition of BSE, although some isotope tracers suggest that none of the existing chondrite types actually reproduce BSE (Burkhardt et al. 2016). Chondrites are composed of an assemblage of olivine and pyroxenes (silicate minerals) and Fe-Ni metal grains. Excluding the Fe-Ni grains, their composition is very close to that of mantle peridotite. However, during cooling of the solar nebula, moderate and high volatile elements tend to condensate over a large range of temperatures, resulting in elemental fractionation. Only refractory elements (such as Al, Ca, Ti) condensate in a narrow range of temperatures and thus their original "solar" elemental ratios are mostly preserved. Si and Mg, which are important constituents of the BSE, are in between the refractory and the moderate volatile elements, and thus partially fractionated. Thus, the undifferentiated meteorites only allow determining precisely the ratios of refractory lithophile elements in the Earth's primitive mantle (Jagoutz et al. 1979).

Hydantoin formation

Definition

The Bücherer-Bergs synthesis (Ware 1950) of ► [hydantoins](#) is carried out by reacting cyanohydrins (the addition products of cyanide anion to aldehydes or ketones) with ammonium carbonate (or CO_2 and NH_3). Its mechanism, closely related to the ► [Strecker synthesis](#), involves α -aminonitriles as intermediates that

are processed via a carbon dioxide-promoted reaction (Fig. 1) (Pascal et al. 2005).

The Hydantoins can be ring-opened hydrolytically to form N-carbamoylamino acids. It is considered relevant to amino acid formation on the early Earth because it is likely to have prevailed over Strecker synthesis in a CO_2 -rich atmosphere. Peptides are potentially produced through conversion of N-carbamoylamino acids to amino acid N-carboxyanhydrides (Pascal et al. 2005) (Fig. 1).

C₃N[−] Anion

Marcelino Agúndez
Instituto de Física Fundamental, CSIC, Madrid,
Spain

Synonyms

[Cyanoacetylide anion](#)

Chemical Formula

C₃N[−]

Definition

The negative ion C₃N[−] is a closed-shell species isoelectronic with cyanoacetylene (HC₃N). The characterization of its rotational spectrum in the laboratory allowed to detect it in the carbon-rich circumstellar envelope IRC + 10216 (Thaddeus et al. 2008) and, later on, in the cold dark cloud TMC-1 (Cernicharo et al. 2020). In circumstellar and interstellar clouds, it is thought to be formed by radiative electron attachment to the radical C₃N (Millar et al. 2017). The anion C₃N[−] was also tentatively identified in the upper atmosphere of Titan, where it is thought to be produced by photochemistry (Vuitton et al. 2009; Dobrijevic et al. 2016).

Chemical Formula

C₅N[−]

Definition

The negative ion C₅N[−] is a closed-shell species isoelectronic with cyanodiacetylene (HC₅N). It was assigned, based on high-level ab initio calculations, to a series of harmonically related lines in the carbon-rich circumstellar envelope

IRC+10216 (Cernicharo et al. 2008) and in the cold dark cloud TMC-1 (Cernicharo et al. 2020). In circumstellar and interstellar clouds, it is thought to be formed by radiative electron attachment to the radical C_5N (Millar et al. 2017). The anion C_5N^- has been also tentatively identified in the upper atmosphere of Titan, where it is thought to be produced by photochemistry (Vuitton et al. 2009).

CAB, Spain

Michel Viso

Innovaxiom, Paris, CX, France

Definition

The Spanish Centro de Astrobiología (CAB) was created as a Joint Center between CSIC (Consejo Superior de Investigaciones Científicas) and the Spanish space agency INTA (Instituto Nacional de Técnica Aeroespacial) with the support of the Comunidad Autónoma de Madrid (CAM). The main goal of the CAB is to provide a truly trans-disciplinary research environment for the development of the new science of Astrobiology. The CAB operates with the specific new contribution of a common methodology based on complexity theory and the application of the scientific method to understanding the origin of life by exploring the habitability conditions on Earth and beyond, within the Solar System, or in extra-solar planets. CAB scientific activities started in late 1999 at temporary buildings, while awaiting a new building to be constructed and equipped. The new CAB premises were inaugurated in January 2003.

CAB is located within the campus of INTA and, in addition, has one astronomical facility with a robotic telescope at the Observatorio Astronómico Hispano-Alemán de Calar Alto (CAHA). CAB's scientists and engineers are deeply involved in space missions such as MSL, ► [ExoMars](#), INTEGRAL, Bepi Colombo, PLATO, HERSCHEL, and SPICA.

History

The origin of the CAB goes back to a proposal presented to NASA in 1998 by a group of Spanish and American scientists, led in Spain by Juan Pérez-Mercader, to join the newly created NASA Astrobiology Institute (NAI). The group was integrated within the ► [NAI](#) as a full Associate Member in 2000. Following an

exchange of letters at Government level, CAB became the first Associate Member of NAI outside the US. The other NAI Associate Member since 2003 is the Australian Centre of Astrobiology.

Chondrites · Chronology · Inclusions

Synonyms

[Calcium-aluminum-rich inclusions](#)

Definition

CAIs (calcium-aluminum-rich inclusions) are white inclusions found in carbonaceous chondrites. They are made of calcium- and aluminum-rich oxides and silicates. They are among the oldest solids of the solar system. They provide clues on the immediate environment of the nascent solar system and on its earliest phases.

Overview

CAIs were discovered in the Vigarano ► [chondrite](#) by M. Christophe Michel-Levy in 1968.

They are an assemblage of calcium and aluminum oxides and silicates, i.e., spinel, hibonite, grossite, melilite, anorthite, and calcium- and aluminum-rich pyroxenes. CAIs are enriched in refractory elements by a factor of 10–100 relative to bulk chondrites. They have variable textures: irregular, fluffy, round, and compact. Some CAIs show evidence of melting, probably during chondrule formation. Others exhibit evidence of reprocessing in the chondrite parent bodies. CAIs are enriched in oxygen-16 relative to chondrites. Some of them are enriched in the heavy isotopes of magnesium and silicon. They often are isotopically anomalous relative to the bulk solar system. These anomalies, at the level of a few hundred ppm, were found mostly in neutron-rich isotopes, such as ^{48}Ca or ^{50}Ti . They contain a high abundance of short-lived radionuclides (see entry ► [Cosmochemistry](#)). Their Pb-Pb absolute ages (about 4,567 Ma) are older than those of chondrules or differentiated meteorites.

CAIs are very abundant in carbon-rich carbonaceous chondrites, while they are virtually absent from other chondrites. Studies of CAIs during the last 30 years are heavily biased toward CAIs found in the CV3 chondrites epitomized by the Allende meteorite which fell in Mexico in 1969. The reason for that bias is that CAIs in CV3 chondrites are large (up to a cm) and abundant (~10% volume). It is, however, important to note that CAIs in CV3 chondrites are quite peculiar when compared to CAIs in other chondrite groups and may record specific events in the solar protoplanetary disk. More studies should and will be dedicated to CAIs in other chondrite groups. A few CAIs were found among the dust brought back by the Stardust spacecraft from comet Wild 2.

Most CAIs probably formed by condensation. Some of them endured severe evaporation. Because of their old age, the extent of the isotopic anomalies they bear, and their richness in short-lived radionuclides, they are believed to be the first solids to have formed in the solar

protoplanetary disk. As such, they record the earliest phases of solar system formation. Short-lived radionuclides as well as isotopic anomalies record nucleosynthesis processes in generations of stars prior to the solar system. Some short-lived radionuclides also record irradiation processes in the early solar system. Because they formed at high temperature, in a gas-poor region, they are believed to have formed close (0.1 AU) to the protosun. They were transported to chondrite formation distances either by winds powered by the magnetic interaction between the Sun and the disk or by turbulence.

Callisto

Therese Encrenaz
Observatoire de Paris, PSL, CNRS, Sorbonne University, University Paris-Diderot, Meudon, France

Definition

Callisto is a satellite of Jupiter discovered by ► [Galileo Galilei](#) in January 1610; it is the outermost of the Galilean satellites. With a radius of 2,410 km, Callisto is, after Ganymede and Titan, the third biggest satellite in the solar system. Its distance to ► [Jupiter](#) is 1,882,700 km or 26 Jovian radii. Its density is 1.8 g/cm³, typical of icy objects. Callisto has been investigated by the Voyager 1 and 2 spacecraft in 1979, then by the Galileo orbiter between 1995 and 2003. The surface of Callisto is heavily cratered and consists of a mixture of ice and dust. A great basin, Valhalla, over 500 km in diameter, is the signature of a large major impact. As in the case of Ganymede, a liquid ocean could exist below the icy crust. Callisto is expected to be explored by the European JUICE mission, planned for arrival in the Jovian system in 2031.

Calvin's Conception of Origins of Life

Stéphane Tirard
Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

History

Melvin Calvin (1911–1997) was an American biochemist, who discovered, with Andrew Alm Benson (1917–), the cycle of reactions in the obscure phase of photosynthesis during the 1940s (Calvin-Benson cycle). Calvin obtained the Nobel Prize in 1961 for this discovery.

In 1951, Calvin published one of the first works in prebiotic chemistry. He reduced carbon dioxide in aqueous solution, by ionizing radiation, to formic acid.

In 1953, Harold Clayton Urey (1893–1981) rejected this result because of the presence of CO₂. Urey was in favor of a reductive primitive atmosphere without CO₂. However, Calvin maintained his interest for origins of life during the rest of his career and published his main book on this topic in 1969 (*Molecular Evolution towards the Origin of Living Systems on Earth and Elsewhere*).

Calvin-Benson Cycle

Juli Peretó
Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Keywords

Biosynthesis · Autotrophy · Carboxylation · Carbon dioxide

Synonyms

Dark reactions; Reductive pentose phosphate cycle

Definition

A carbon dioxide fixation pathway where a molecule of CO_2 condenses with a 5-C compound (ribulose 1,5-bisphosphate) to yield two molecules of a 3-C compound (3-phosphoglycerate). These 3-C molecules serve both as precursors for biosynthesis and, through a cyclic series of enzymatic reactions, to regenerate the 5-C molecule necessary for the first carboxylating step (Fig. 1). The pathway is present in several bacterial lineages (e.g., cyanobacteria), and its acquisition by eukaryotic cells (chloroplast in algae and plants) was through the endosymbiotic association with ancient cyanobacteria.

History

Melvin Calvin (1911–1997) and coworkers established this autotrophic path of carbon in phototrophic organisms using ^{14}C -labeled carbon dioxide and *Chlorella* (a green algae) cultures (Benson and Calvin 1950). Calvin was awarded with the Nobel Prize in Chemistry in 1961 “for his research on the carbon dioxide assimilation in plants.”

Overview

The Calvin-Benson cycle allows the synthesis of one triose from three molecules of carbon dioxide (Fig. 1): 12 electrons (provided by redox coenzymes like NADH or NADPH) and 9 ATP equivalents are required for bringing CO_2 to the oxidation level of the triose glyceraldehyde 3-phosphate. These fueling requirements are supplied by either a phototrophic or a

Calvin-Benson Cycle, Fig. 1 The Calvin-Benson cycle. The stoichiometry of the cycle allows the net synthesis of one molecule of triose from three molecules of carbon dioxide (gray boxes). Other five trioses (5 C_3) are converted into three pentoses (3 C_5) necessary to initiate the cycle again. The energetic cost for the synthesis of one triose is nine ATP molecules and six reducing equivalents (NADH or NADPH). These energetic requirements could

be satisfied by a photosynthetic apparatus or a chemolithotrophic metabolism. Except for two key enzymatic steps (1 and 2), all the transformations are a combination of enzymes participating in the Embden-Meyerhof-Parnas pathway and the non-oxidative pentosephosphate pathway. Key enzymatic steps: (1) Rubisco; (2) phosphoribulokinase. Abbreviations: Gd3P glyceraldehyde 3-phosphate, DHAP dihydroxyacetonephosphate

chemolithotrophic metabolism. The cycle can be divided into two stages: a reductive carboxylation of the pentose ribulose 1,5-bisphosphate (RuBP) up to glyceraldehyde 3-phosphate and a series of rearrangements of carbon skeletons from trioses to regenerate RuBP throughout 4-, 6-, and 7-C sugar intermediates (Fig. 1). The first step is catalyzed by the key carboxylating enzyme ► [Rubisco](#). As other carboxylases, Rubisco also shows a preference for lighter stable isotopes, and thus CO₂ fixation results in the depletion of ¹³C (δ¹³C) in the biosynthesized organic matter ranging from −20 ‰ to −30 ‰. The second stage of the cycle occurs by the combination of several enzymatic activities from the ► [Embden-Meyerhof-Parnas pathway](#) and the nonoxidative branch of the pentose phosphate pathway.

The Calvin-Benson cycle was originally described in green plant (i.e., chloroplast) photosynthesis (Benson and Calvin 1950). It is also active in endosymbiotic chemolithotrophic proteobacteria of invertebrates living in close proximity to hydrothermal vents. In free-living prokaryotes, this pathway has been demonstrated in cyanobacteria (the group to which the ancestors of plastids belonged), some aerobic or facultative anaerobic proteobacteria, CO-oxidizing mycobacteria, diverse iron-sulfur-oxidizing firmicutes, and in some green sulfur bacteria. Although Rubisco has been isolated from some Archaea, there is no evidence for the operation of the full cycle in autotrophic species from this domain (Berg et al. 2010).

Campbellrand-Malmani Platform, South Africa

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

The Campbellrand-Malmani carbonate platform was deposited on the ► [Kaapvaal craton, South Africa](#), between 2,588 and 2,520 Ma (Neoproterozoic). This 1.9-km-thick carbonate platform is preserved over at least 190,000 km² and probably originally covered the entire extent of the Kaapvaal craton (~600,000 km²). The Campbellrand-Malmani is the first extensive carbonate deposit of the Neoproterozoic, prior to the buildup of oxygen in the ocean and atmosphere about 2.35 Ga ago. The abundance of aragonite pseudomorphs in this unit suggests a neutral to slightly alkaline ocean, which in turn may indicate a low atmospheric CO₂ concentration.

Canadian Precambrian Shield

Phil Thurston

Laurentian University, Sudbury, ON, Canada

Keywords

Accreted terrane · Accretion · Craton · Geological province · Magmatic arc · Supercontinent cycle

Synonyms

[Canadian shield](#); [North American shield](#)

Definition

The Canadian ► [Shield](#) is the region of North America underlain by Precambrian rocks (>542 Ma), extending from the Arctic Ocean to the Great Lakes and further south and west in the subsurface (Fig. 1).

Overview

The Canadian Precambrian Shield is subdivided into geological provinces (regions of similar age). The major Archean (>2.5 Ga) provinces are the Slave (S), Superior (Sup), Rae (R), and Hearne (H). All of them have a similar architecture: linear sub-provinces or belts of fine-grained sediment and subaqueously erupted volcanic rocks which are surrounded and cut by granites (Hoffman 1989). In detail, the Superior province consists of an old (~3 Ga) core (NCT) surrounded by linear belts of volcanic rocks that alternate with granites and belts of sedimentary rocks which become younger (2.9 to ~2.7 Ga) north and south of the core (Percival 2007). This architecture suggests the Archean provinces (pink on Fig. 1) grew as successively younger belts of volcanic and volcano-sedimentary rocks added to the continental margin by plate-tectonic processes. This was followed by the intrusion of much granitic rock during the interval 2.7–2.6 Ga, transforming the Archean provinces into a comparatively light, buoyant ► [craton](#). The crustal thickness of the cratons is typically ~40 km. The cratonization processes involved the development of large-scale faults that brought gold-bearing fluids from deep in the Earth to the near-surface environment. Several cratons of this age (2.7 Ga) joined to form the ► [supercontinent](#) “Kenorland” (Aspler and Chiarenzelli 1998). The edges of Kenorland include some much older (~3.8 Ga) fragments (red units on Fig. 1) that were accreted onto the margin of the supercontinent. Kenorland broke apart by the development

Canadian Precambrian Shield, Fig. 1 Subdivisions of the Canadian Shield of North America based on the age of the rock unit. Archean cratons and subdivisions within: *Sup* Superior craton, *NSS* Northern Superior superterrane and Hudson Bay terrane, *RA* Riviere Arnaud terrane, *NCT* North Caribou terrane, *M* Marmion terrane, *N* Nain craton,

S Slave craton, *R* Rae craton, *H* Hearn craton, *Wy* Wyoming craton, *GC* Grouse Creek block. Paleoproterozoic (2.5–1.6 Ga) tectonic domains after Ross (2002) and Aspler et al. (2003); *Hu* Huronian, *T* Taltson, *B* (brown) Buffalo Head, *B* (green) Great Bear, *H* Hottah, *Fs* Fort Simpson, *W* Wabamun, Chinchaga and Ksituan terranes

of 2.48–2.10 Ga old rifts containing dikes and volcanic rocks followed by the deposition of uranium-bearing, dominantly sandy continental margin sedimentary units [e.g., Hu in brown on Fig. 1, on the south edge of the Superior craton]. The various Archean cratons then drifted apart and became separated by ocean basins and island arcs. The oceans later closed, and the various accreted terranes and 2.0–1.8 Ga volcanic arcs accreted onto the margins of the Archean cratons to form the “Columbia” supercontinent (Zhao et al. 2004). During the interval 1.8–1.2 Ga, Columbia grew by the accretion of multiple belts, again consisting mostly of volcanic and granitic rocks along its southern and eastern margins, e.g., the Yavapai-Central Plains belt [Y on Fig. 1, (1.8–1.7 Ga)], the Mazatzal (M) (1.7–1.5 Ga) belt in the USA, the Labradorian belt of Quebec and Labrador, and the 1.3–1.0 Ga Grenville Province (G on Fig. 1) (Karlstrom et al. 1999).

Cap Carbonates

Emmanuelle J. Javaux
Palaeobiogeology-Palaeobotany-
Palaeopalynology, Geology Department,
Université de Liège, Liège, Belgium

Definition

Cap carbonates are a special type of laminated carbonate rocks (limestone and/or dolostone) associated with glacial deposits in the Neoproterozoic (► [Snowball Earth](#)). They sharply overly (“cap”) unsorted glacial sediments called tillites. Their origin is not well understood, but they may be related to a particular ocean and

atmosphere chemistry with high CO₂ concentration and alkalinity from silicate weathering or to upwelling of highly alkaline deep waters following deglaciation. They are associated with negative incursions of carbon isotopes that are widespread and can serve for correlation.

Definition

Carbohydrates are molecules composed solely of carbon, oxygen, and hydrogen with the general formula $C_n(H_2O)_n$. The ratio of carbon to hydrogen to oxygen atoms in a carbohydrate is 1:2:1. Carbohydrates are involved in cell signaling, serve as a source of energy, and provide structure to cells. Chains that alternate negatively charged phosphates with carbohydrates form the backbones of the genetic biopolymers RNA and DNA.

Overview

Carbohydrates are an essential component of life on Earth. From ► [ribose](#) being an integral component of the genetic biopolymers DNA and RNA to polymers of glucose used for cell wall support in plants, carbohydrates are involved in many crucial biological functions. The complex structures of carbohydrates can be easily visualized using ► [Fischer projections](#). Figure 1 depicts Fischer projections of aldoses, a class of carbohydrates that contain an aldehyde group. In the structures below, each line represents a covalent bond and each intersection of lines represents an unwritten carbon (C).

There are 2^n stereoisomers of a given sugar, where n is the number of ► [chiral](#) centers in the molecule. For instance, the aldopentoses contain five carbons, three of which are chiral centers, giving $2^3 = 8$ stereoisomers. These pentoses have the common names of ribose, arabinose, xylose, and lyxose and each come in a d or l ► [enantiomer](#). The d or l configuration of the sugar is determined by the position of the alcohol on the chiral center furthest away from the aldehyde carbon. If the alcohol is on the right of the backbone, the sugar is classified as d, while if it is on the left, it is l. In the case of aldopentoses, this chiral center is on carbon four (Fig. 2). On Earth, the d isomer prevails as the dominant carbohydrate incorporated in biological systems; however, it has been postulated that l sugars could also be used as the predominant isomer in alternate “alien” biochemistries.

Carbohydrate, Fig. 1 The four-, five-, and six-carbon d-aldoses

Carbohydrate,

Fig. 2 Carbohydrates can occur in either D or L forms. The ketose ribulose has an oxidized center at carbon two

Carbohydrates can also form cyclic structures that produce an anomeric center giving the sugar an alpha (alcohol pointing down) or beta (alcohol pointing up) label. Ribose, for example, can be found in a furanose (five-membered) or pyranose (six-membered) form. Both the alpha and beta configurations of the furanose and pyranose forms of ribose are shown in Fig. 3. The ribose found in DNA is in a furanose configuration, whereas ribose in aqueous solutions and

crystalline form is predominantly pyranose (Šišak et al. 2010).

Presence of Carbohydrates in the Universe

Astrobiologists studying the ► [origins of life](#) seek an answer to fundamental questions related to the origins of carbohydrates. Through the use of radio telescopes, scientists have determined the presence of carbohydrates and their building blocks in interstellar gas clouds. Examples of some organic

molecules reported in these clouds (Fig. 4) include ► **formaldehyde**, ► **glycolaldehyde**, and dihydroxyacetone (Snyder et al. 1969; Hollis et al. 2004; Weaver and Blake 2005; although the detection of dihydroxyacetone has been questioned – see ► **Molecules in Space**). Meteoritic bombardment could have delivered these molecules to the surface of the early Earth (Sephton 2002). Aldol reactions of glycolaldehyde and formaldehyde on a primitive Earth could also have been sources of glyceraldehyde, erythrulose, and higher carbohydrates (Fig. 5).

Prebiotic Synthesis of Carbohydrates

The prebiotic synthesis of carbohydrates is fundamental to astrobiology and origins of life research.

The ► **“RNA World”** hypothesis, which purports that life evolved from simple RNA molecules, presupposes the existence of a prebiotic soup with abundant building blocks, including amino acids, carbohydrates, purines, and pyrimidines.

One of the first reported instances of prebiotic carbohydrate synthesis occurred in 1861 when a German scientist, Butlerov, added formaldehyde to hot solutions of barium and calcium hydroxide forming a sweet sugary substance (Butlerov 1861). This became known as the ► **formose** reaction. A century later, Breslow discovered that the glycolaldehyde formed in this reaction initiates a series of autocatalytic reaction cycles which, over time, fix more formaldehyde to give higher carbohydrates (Breslow 1959). A side reaction in this

experiment is the disproportionation of [formaldehyde](#) to form [methanol](#) and formic acid in a process now known as the Cannizzaro reaction (Fig. 6).

One argument against the RNA world arising from the [primordial soup](#) involves the formation of “problematic tar,” which is a seemingly useless by-product of highly reactive species (Larralde et al. 1995). The propensity of the formose reaction to form tar is an indication of the functionality and reactivity of these building blocks. The tar prevents the accumulation of genetically relevant carbohydrates and complicates in-depth product analysis. Recently, however, [borate](#) minerals have been shown to stabilize and direct the reactivity of carbohydrates, making them potentially important participants in prebiotic reactions (Ricardo et al. 2004). Here, borate binds to adjacent alcohols of sugars as they are formed. This in turn reduces their reactivity and improves carbohydrate stability, preventing further uncontrolled tar-forming reactions.

In a different approach to prebiotic carbohydrate synthesis, activated pyrimidine nucleosides are assembled, sidestepping the model of adding a nucleobase to a previously synthesized ribose sugar (Powner et al. 2009). Though this methodology does not yet account for the synthesis of purine nucleosides, it opens new avenues for research toward the prebiotic synthesis of RNA and DNA.

Elemental carbon

Definition

Carbon: The sixth element of the periodic table.

Overview

Carbon is the sixth element in the periodic table. Its stable isotopes include ^{12}C , the nucleus of which contains six protons and six neutrons, and ^{13}C , which contains six protons and seven neutrons. Carbon is the fourth most abundant element in the solar atmosphere, after hydrogen, helium, and oxygen. This predominance is largely due to the autocatalytic role of carbon in the stellar nucleosynthesis of elements higher than hydrogen via proton addition (Bethe 1939):

Carbon Isotopes

Carbon exists on Earth in the form of two stable (^{12}C and ^{13}C) and one unstable isotope (^{14}C). ^{12}C and ^{13}C have abundances of 98.89% and 1.108%, respectively (Wederpohl 1978). The standard atomic weight of carbon on Earth (abridged to five figures) is, therefore, 12.011 (Commission on Isotopic Abundances and Atomic Weights,

IUPAC). ^{14}C (six protons and eight neutrons) is produced in the upper atmosphere by the interaction of thermal neutrons (produced from cosmic rays) and nitrogen atoms. The isotope has a half-life for decay (into ^{14}N and a beta particle, β^-) of 5730 years and is employed in determining the age of objects having a biological origin up to about 50,000 years of age (Arnold and Libby 1949). In addition to the use of ^{14}C decay kinetics to determine the age of objects of archeological and anthropological interest, the ratio of the stable isotopes $^{12}\text{C}/^{13}\text{C}$ is an important indication of the pathway of synthesis of organic compounds. Because of the kinetic isotope effect, both biological and nonbiological synthetic processes can produce organic material containing a distinctive enrichment of the lighter isotope of carbon, ^{12}C . While the isotopic fractionation ratio ($\delta^{13}\text{C}$) was once thought to be a reliable indication of a biological carbon fixation (Schidlowski et al. 1983), this has recently been questioned (McCollom and Seewald 2006).

Electronic Structure

The electronic structure of carbon is abbreviated as $1s^2, 2s^2, 2p^2$ (two electrons in the $1s$ orbital, two electrons in the $2s$ orbital, and two electrons in the $2p$ orbital). The element can therefore accept four electrons in the outermost (valance) shell to complete an octet and form a neon-like configuration: $1s^2, 2s^2, 2p^6$. It was pointed out by Wald that the prevalence of H, O, N, and C in biochemistry can be rationalized by the fact that these elements are the smallest that can reach stable (filled, i.e., noble gas-like) electronic configurations in the valance shell by adding (i.e., sharing with other atoms) one, two, three, and four electrons, respectively, and thereby forming covalent bonds (Wald 1958).

This suggests that the same properties of these elements would similarly be responsible for a central role for organic chemistry (and biochemistry) anywhere in the universe. Wald also argued that silicon's electronic configuration (one period lower in the periodic table; $1s^2, 2s^2, 2p^6, 3s^2, 3p^2$), while potentially also permitting the forming

of covalent bonds by accepting four electrons in the outermost shell, is substantially larger than carbon. The larger distance between the nucleus of silicon and the outer electronic orbitals results in differences in bonding energies, as well as the geometry of the orbitals, compared to carbon. The result is that C forms stable covalent bonds (single as well as multiple) with itself and with other atoms, while Si has much less tendency to do so. Thus, CO₂ is a discrete molecule and a stable gas, and C-C bonds produce stable chains of hydrocarbons. SiO₂, on the other hand, is a crystalline solid (of average composition SiO₂), which exists as an unlimited three-dimensional network, and Si-Si chains are not stable in the presence of water or O₂. Carbon is thus regarded by most astrobiologists as being central to and probably necessary for life.

Native Forms of Carbon

In spite of its importance to life and its role in the biosphere, elemental carbon is only a trace constituent in most of the Earth's crust, where it is present at an average level of 200 ppm. In sedimentary rocks, carbon is abundant but usually in compounds such as carbonates (limestone) or organic matter (petroleum, coal). In the biosphere, hydrosphere, and atmosphere, carbonic acid equilibria (carbon dioxide, carbonate, and bicarbonate) play major roles in the weathering of crustal rocks and presumably would have similar roles on other, Earth-like planets.

The primary forms of elemental carbon in Earth's crust and mantle are graphite and diamond. Diamond is thought to form under high-pressure and high-temperature conditions in the mantle and to be transported to the surface by magmatic activity. Graphite has a sheet-like network of so-called sp² (planar)-bonded carbon atoms (see below) and can be hydrogenated to produce hydrocarbons or oxidized to carboxylic acids. In contrast, diamond, which has a tetrahedral or sp³ structure, forms face-centered cubic crystals which are difficult to oxidize or reduce. The hexagonal mineral lonsdaleite, another allotrope which is said to be even harder than

diamond, is only found in strongly shocked areas such as meteorite craters, where it is thought to have formed from graphite during impact (Wederpohl 1978). Similarly, fullerenes and related "cage" forms of carbon also require exceptional conditions to form but have been identified in the unshocked Allende and Murchison meteorites as C₆₀–C₄₀₀ fullerenes (Becker et al. 2000). Graphene, a linear sheet structure consisting of hexagonal lattices of carbon, has long been recognized as a theoretical possibility, but was only synthesized in 2004 (Novoselov et al. 2004). It forms the basis for a new series of sheet structures and can be thought of as the basic unit of fullerenes. Similarly, carbon nanotubes have been described in which graphene sheets comprise the basic structural unit. For a review of these structures see Hirsch (Hirsch 2010).

Compounds of Carbon and the History of Organic Chemistry

Although the element has been known from ancient times, an understanding of its chemical nature and particularly its role in organic material did not emerge until the development of analytical methods by Lavoisier and others in the eighteenth century. Thus, Lavoisier demonstrated that carbonic acid or carbon dioxide was formed by the union of carbon and oxygen or by burning organic substances in air or oxygen (Moore 1918). The terms "organic chemistry" and "organic compound" were historically intended to indicate the nature of biologically derived compounds of carbon, which were thought to be unique to life. Today, organic chemistry is usually described as the chemistry of compounds of carbon but probably can be more accurately regarded as focusing on the chemistry of hydrocarbons (compounds composed of hydrogen and carbon) and of their derivatives with oxygen and nitrogen.

Modern organic chemistry is generally considered to have started in the mid-nineteenth century with the work of Wöhler, who synthesized the well-known animal waste product, urea. The actual story of Wöhler's work is somewhat more

complicated than the usual description. The great chemist was attempting to synthesize ammonium cyanate by studying the reaction between cyanogen and (aqueous) ammonia, one of the products of which was a white crystalline substance. The same product was also obtained by the reaction of lead cyanate and ammonia. It was in the course of purifying the latter that Wöhler obtained urea. His realization of the potential importance of the reaction led him to write to Berzelius, saying that he could make urea without using a kidney or even an animal (McKie 1944). In spite of the enthusiastic nature of this communication to Berzelius, the latter's reaction, as well as those of many of Wöhler's contemporaries, was restrained and ► [vitalism](#) only gradually died out.

During this same period, chemists became aware of the existence of meteorites containing organic compounds. Berzelius and Wöhler, among others, remarked on the presence of organic material in several carbonaceous meteorites. It is noteworthy, however, that neither Berzelius nor Wöhler thought that the organic compounds present were necessarily biological products (Nagy 1975). Today, the universality of organic chemistry has become obvious, not only through the investigation of meteorites and comets but due to observations of interstellar organic compounds.

Molecular Structure of Carbon Compounds

Bond formation between carbon atoms (or with other elements) occurs by sharing electrons and involves a process known as hybridization of molecular orbitals. In methane and related hydrocarbons, the carbon atom is located in the center of a tetrahedron, with the bonded hydrogen atoms located at the corners. This geometry was explained by Pauling:

We have thus derived the result that an atom in which only *s* and *p* eigenfunctions contribute to bond formation and in which the quantization in polar coordinates is broken can form one, two, three, or four equivalent bonds, which are directed toward the corners of a regular tetrahedron. (Pauling 1931).

The tetrahedral geometry of compounds of carbon thus results from so-called sp^3 hybridized orbitals. As a consequence of this symmetry, substitution of other atoms bonded to the central carbon atom (such as substitution of the hydrogen atoms in methane, CH_4 by atoms or groups A, B, and C to produce $CHABC$), produces an unsymmetrical molecule which displays the phenomenon of ► [chirality](#). Synthesis of such a chiral molecule by a spontaneous chemical reaction produces a mixture of isomers or enantiomers which are chemically but not physically identical. It can readily be seen by inspecting models that such simple examples of chiral enantiomers are mirror images of each other. The phenomenon of chirality was discovered historically by Pasteur, in the form of "optical activity," as determined by the property of rotating the plane of polarization of a plane-polarized beam of light. The carbon atom in this simple compound is referred to as an asymmetric center. More complex molecules, such as the biological product tartaric acid, which led Pasteur to his discovery, contain more than one chiral center and can produce even more complicated sets of chiral enantiomers.

Definition

The carbon cycle is one of the most important biogeochemical cycles on Earth and involves all five environmental spheres. Its geological components operate on a scale of millions of years, while biological carbon cycling operates over a scale of days to thousands of years. Every organism on Earth needs carbon either for structure or energy, and the primary biological processes in carbon cycling are ► [photosynthesis](#) and respiration. Incorporation of biological carbon in sedimentary deposits subsequently used as fossil fuels is now also an important process in biological carbon cycling, notably through influencing the global carbon budget and thus the Earth's climate.

Overview

Carbon is the fourth commonest element in the Universe and is present in all five Earth spheres (► [biosphere](#), geosphere, pedosphere, ► [hydrosphere](#), and atmosphere). The annual rates of biological carbon cycling are several orders of magnitude greater than geological cycling of carbon and very responsive to environmental fluctuations. Carbon is essential to life on Earth, and the biological processes of light-mediated carbon fixation (photosynthesis, chemolithoautotrophy), ► [aerobic respiration](#) of organic carbon to form inorganic CO₂, and (to a lesser extent) ► [anaerobic respiration](#) to form methane (and some CO₂) are important mechanisms for processing carbon within the five spheres. Exchange of carbon between land and atmosphere is driven by the key biological processes, but in the oceans is dominated by physical exchange as the world's oceans hold vast quantities of dissolved inorganic carbon. This reservoir of dissolved inorganic carbon (DIC) is relatively dynamic, but other reservoirs are more stable. In the case of terrestrial carbon cycling, low rates of decomposition can result in accumulation of organic carbon (e.g., peat deposits, bogs) which can under certain geological conditions form substantial coal, oil, and

gas (including methane hydrate) deposits. In the oceans, sedimentation of plankton with calcareous skeletons results in burial and limestone formation though this can also form through reaction of carbonate ions with calcium. This range of organic and particularly inorganic carbon deposits represents significant long-term sinks for atmospheric CO₂. Anthropogenic activities significantly contributing to carbon cycling include burning of fossil fuels and agro fuels and industrial processes, such as cement production (limestone decomposition). The observed buildup of CO₂ in the atmosphere since the start of the industrial revolution and associated regional warming has led to warmer ocean surface waters. Warmer waters absorb less CO₂, and so the “braking” effect of the oceans on rising atmospheric CO₂ concentrations is reduced. Warming also allows potential release of methane from temperature-sensitive methane hydrate deposits within shallow marine sediments and from thawing permafrost peat deposits on land, as well as extending the active season for soil respiration, further enhancing release of carbon dioxide and methane to the atmosphere.

Carbon Dioxide

Thomas McCollom

Laboratory for Atmospheric and Space Physics,
University of Colorado, Boulder, CO, USA

Keywords

Carbon cycle · Carbon fixation · Carbon-silicate cycle · Greenhouse effect

Synonyms

CO₂

Definition

Carbon dioxide is a triatomic compound with the chemical composition CO₂. The molecule is symmetrical and nonpolar. The triple point of pure CO₂ occurs at −56.6 °C and 518 kPa (Fig. 1). As a gas, carbon dioxide is clear, colorless, and odorless.

Overview

Carbon dioxide occurs predominantly as either a gas or a solid ice in the solar system. As a gas, it is the predominant constituent of the atmospheres of Venus and Mars, as well as a minor component of the atmospheres of many other planetary bodies including the Earth. As an ice, CO₂ is a significant component of comets and the Martian polar caps. Liquid carbon dioxide requires temperatures above −56 °C and pressures greater than 5 bar (Fig. 1) to exist. Such conditions are not presently known to occur in the solar system, but might have been present on early Mars and may occur on extrasolar planets. Carbon dioxide has been found in interstellar clouds in gas and ice phases by the Infrared Space Observatory (ISO).

Carbon dioxide is also present in the interior of the Earth, where it occurs as a trace component within the crystal structures of minerals or

Carbon Dioxide,
Fig. 1 Phase diagram for
 pure carbon dioxide

occupies void spaces between minerals. At the oxidation state of the Earth's mantle, carbon dioxide together with the minerals graphite and diamond is the predominant stable form of carbon. Carbon dioxide dissolves into magmas as they form within the Earth's interior and is released into the atmosphere when the magmas cool and solidify as volcanic rocks at the surface. As a consequence, carbon dioxide is a major component of volcanic gases and is the primary form of carbon in those gases. Carbon dioxide that accumulates in the atmosphere contributes to the ► [greenhouse effect](#) that plays a significant role in warming of planetary surfaces.

Carbon dioxide dissolves readily in water, where it hydrates to form carbonic acid ($\text{H}_2\text{CO}_{3(\text{aq})}$), which in turn generates acidity through the release of protons ($\text{H}_2\text{CO}_{3(\text{aq})} \rightarrow \text{H}^+ + \text{HCO}_3^- \rightarrow 2\text{H}^+ + \text{CO}_3^{2-}$). The protons released can react with minerals to cause rock weathering, altering the rock's mineralogy and releasing cations such as Ca^{2+} and Mg^{2+} into solution. Under some circumstances, the cations released can react with dissolved CO_2 to precipitate as carbonate minerals including calcite (CaCO_3) and siderite (FeCO_3) as part of the carbon-silicate cycle. The net result is the removal of atmospheric CO_2 into carbonate-bearing rock.

Some biological organisms, the photoautotrophs and chemoautotrophs, are capable of transferring electrons to carbon dioxide (CO_2 ► [reduction](#)) to form bioorganic compounds, a process termed carbon fixation. Conversely, heterotrophic organisms consume bioorganic matter and convert much of it back to carbon dioxide in a process known as ► [respiration](#). Transformation of CO_2 through carbon fixation and respiration is a primary component of the biological carbon cycle.

Keywords

Carbon isotopes · Solar system · Carbon cycle · Biosignature

Definition

Carbon has two naturally occurring stable isotopes, ^{12}C and ^{13}C . In addition, there is a radioactive isotope ^{14}C , with a half-life of 5730 ± 40 years. The radioactive ^{14}C is formed in trace amounts in the atmosphere as a result of cosmic ray bombardment.

Materials of the Milky Way Galaxy have large primordial variations in the relative abundance of the carbon isotopes. These compositions are usually reported as $^{12}\text{C}/^{13}\text{C}$ ratios, which differ from the convention adopted for Solar System materials. For Solar System materials, the range of the isotopic composition of carbon is much more limited, and the abundances of isotopes are measured and reported as parts per 1000 deviations of the $^{13}\text{C}/^{12}\text{C}$ ratio of the sample from that of the international Vienna Pee Dee Belemnite (VPDB) reference standard. These relative deviations are expressed in δ -values:

$$\delta^{13}\text{C} = (R_{\text{sample}}/R_{\text{VPDB}} - 1) \times 1000, \quad (1)$$

where R is the abundance ratio of ^{13}C to ^{12}C . The numeric values are given in permil units followed by the ‰ symbol.

Physical, chemical, and biological processes cause fractionation in the relative abundance of ^{13}C and ^{12}C between substances. The distribution of ^{13}C and ^{12}C between two interacting

substances A and B is expressed with a fractionation factor α , which is defined as the ratio of the $^{13}\text{C}/^{12}\text{C}$ ratios of the two substances A and B:

$$\begin{aligned} \alpha_{A-B} &= \left(^{13}\text{C}/^{12}\text{C} \right)_A / \left(^{13}\text{C}/^{12}\text{C} \right)_B \\ &= (1000 + \delta^{13}\text{C}_A) / (1000 + \delta^{13}\text{C}_B). \end{aligned} \quad (2)$$

The fractionation factor is often given using a derived quantity $1000\ln\alpha$, especially when addressing equilibrium fractionation processes. Between most terrestrial substances, the fractionation factor α_{A-B} is close to 1, and the difference in $\delta^{13}\text{C}$ values gives a useful approximation of $1000\ln\alpha$:

$$\Delta_{A-B} = \delta^{13}\text{C}_A - \delta^{13}\text{C}_B \approx 1000 \ln \alpha_{A-B}. \quad (3)$$

Another derived quantity to quantify fractionation is ϵ_{A-B} , which is defined as

$$\epsilon_{A-B} = (\alpha_{A-B} - 1)1000. \quad (4)$$

Because $\alpha_{A-B} \approx 1$, also $\epsilon_{A-B} \approx \Delta_{A-B}$. The ϵ value is commonly used to designate fractionation in kinetic, nonequilibrium processes.

History

The name carbon is derived from the Latin *carbo* for “charcoal.” Aston (1920) was the first to document the ^{12}C isotope, which he considered to be the only isotope of carbon. Subsequently, King and Birge (1930) established the existence of a minor ^{13}C isotope using a mass spectrograph. Nier and Gulbransen (1939) reported carbon isotope ratios of air, organic matter, coal, graphite, diamond, meteorite, and carbonates. They noticed significant differences in carbon isotope composition among these materials, with plants, coal, air, and oil being enriched in ^{12}C with respect to carbonates. However, these measurements were not sufficiently precise and accurate to address geological problems.

Nier (1940) introduced a 60°-sector field mass spectrometer, which was further improved by McKinney et al. (1950) in the effort of Harold Urey's group to develop an oxygen isotope paleothermometer. In the same paper, they also adopted the delta notation with the isotope ratios expressed as relative permil deviations from a reference standard. The PDB scale was defined with calcite of cephalopod, *Belemitella americana*, from the Pee Dee Formation of South Carolina by Urey et al. (1951). This work set up the ground for the expansion of carbon isotope studies to many different fields, including geochemistry, paleoclimatology, hydrology, plant science, ecology, archeology, planetary studies, and astrobiology. New analytical methods have extended the analyses to exceedingly small amounts of carbon and in situ analytical techniques allow analyses to be made directly on the surface of the sample.

Overview

Carbon Isotope Fractionation

Equilibrium fractionation describes the redistribution of isotopes of an element among substances under equilibrium conditions. In a carbon isotope exchange reaction, ^{12}C and ^{13}C are exchanged between two substances. The equilibrium state is characterized by the fractionation factor α , generally given as $1000\ln\alpha$. The fractionation factor is strongly dependent on temperature, whereas the effect of pressure is small and can generally be ignored. $1000\ln\alpha$ has the largest absolute values at low temperatures and it approaches zero at high temperatures.

Kinetic fractionation occurs in unidirectional processes and reactions, where the forward and backward reaction rates are not equal. Biological processes are typically unidirectional. For example, a significant kinetic isotope fractionation is associated with the enzymatic carboxylation step of carbon assimilation by plants, in which the plants strongly favor the lighter isotope, ^{12}C .

Basic Methodology

The traditional standard technique for analyzing the isotope composition of carbon involves the analysis of CO_2 on a gas source isotope ratio mass spectrometer (IRMS), where CO_2 is produced either by combustion of organic carbon or acidification of carbonates. The precision and accuracy of the analyses is commonly $<0.1\%$. More recent analytical innovations include tunable diode laser absorption spectroscopy (TDLAS) and cavity ring-down spectroscopy (CRDS). The isotope composition of carbon can also be analyzed in situ on the solid surface of a mineral by secondary ion mass spectrometry (SIMS) or by laser ablation coupled with continuous flow isotope ratio mass spectrometry (LA-CF-IRMS). Organic materials can be analyzed with an elemental analyzer connected to a continuous flow isotope ratio mass spectrometer (EA-CF-IRMS).

Key Research Findings

Presolar Stardust

One of the most astonishing findings in cosmochemistry has been the discovery of presolar stardust grains, including carbon-bearing phases such as diamond, silicon carbide, and graphite (Nittler 2003; Zinner 2014). The evidence for their interstellar, primordial origin is provided by the enormous range in their carbon isotope ratios in comparison to substances formed in the solar system. Presolar graphite and silicon carbide grains have $^{12}\text{C}/^{13}\text{C}$ ratios ranging from 2.1 to 7200 for graphite and from 1.0 to 9500 for silicon carbide (Fig. 1). For comparison, the $^{12}\text{C}/^{13}\text{C}$ ratios in Solar System materials have a much smaller total range of isotope ratios from 84 to 94 (Fig. 1).

The huge carbon isotope range in the stardust grains cannot be explained by physical or chemical fractionation processes. Instead, it is likely to record nucleosynthetic processes within stars as well as during supernova explosions (Nittler 2003). Among all solar system substances, only

Carbon Isotopes in the Solar System, Fig. 1 Distribution of the $^{12}\text{C}/^{13}\text{C}$ ratios in presolar graphite and silicon carbide (SiC) grains. The data are compared

to the total range of $^{12}\text{C}/^{13}\text{C}$ ratios in solar system materials, shown as a grey band. Source of the presolar grain data is the presolar database (Hynes and Gyngard 2009)

these grains carry information about the carbon isotope composition of the presolar stellar environment. Except for the rare stardust grains, the isotopic composition of carbon in the Solar System has been effectively processed and homogenized in the presolar molecular cloud and the early Solar System. In the Milky Way Galaxy, the $^{12}\text{C}/^{13}\text{C}$ ratios of the molecular clouds show an increasing trend with distance from the Galactic center (Milam et al. 2005). Accordingly, planetary bodies formed in different regions of the Galaxy can be expected to have distinct mean carbon isotope compositions.

Bulk $\delta^{13}\text{C}$ of the Solar System

Based on the data from a shuttle-carried Fourier Transform Spectrometer, Lyons et al. (2018) determined that the photosphere of the Sun has a $\delta^{13}\text{C}$ value of $-48 \pm 7\%$ (Fig. 2). Since about 99.8% of the total mass of the solar system is in the Sun, this value also represents the best

estimate for the bulk isotope composition of carbon in the Solar System.

Similar results, although with larger uncertainty, have been obtained for the atmosphere of Jupiter using mass spectrometric methods on the Galileo probe (Niemann et al. 1998) and with SIMS analyses of the interplanetary dust particles (IDPs) (Messenger et al. 2003; Fig. 2). IDPs are thought to be derived from comets and asteroids and represent the most primordial solar system materials, which did not experience significant postaccretional alteration.

CO_2 in Planetary Atmospheres

Atmospheric CO_2 has an important role in maintaining planetary surface temperatures by the greenhouse effect. Record of the isotope composition of carbon in atmospheric CO_2 can provide very useful information about the geological evolution of the atmospheric CO_2 and the carbon cycle on the planet.

Carbon Isotopes in the Solar System, Fig. 2 $\delta^{13}\text{C}$ values of solar system materials. Mean values are shown with error bars (1σ), ranges of data are shown by bars. Separately displayed are the mantle carbon isotope composition for Earth and Mars, and the $\delta^{13}\text{C}$ values of atmospheric CO_2 for Earth, Mars, and Venus. The isotopic composition of carbon in the Sun corresponds to the bulk composition of the solar system, which is shown by a grey horizontal bar. Solar wind implanted C in the lunar regolith

On Earth, the small carbon pool of atmospheric CO_2 is relatively close to carbon isotope equilibrium with a much larger reservoir of dissolved bicarbonate in the surface oceans. The abundance of CO_2 in the atmosphere has increased during the past 200 years from about 280 to 400 ppm. The shift has been accompanied by a decrease in the $\delta^{13}\text{C}$ value of atmospheric CO_2 from ca. -6.5‰ to the present-day value of -8.5‰ (Rubino et al. 2013). Both changes have been caused by anthropogenic fossil fuel emissions.

Information about the isotopic composition of carbon in the atmospheres of Mars and Venus has been acquired by probes and rovers sent to the surface of the planets and by spectroscopic measurements (Fig. 2). A tunable laser spectrometer on board of the Curiosity rover determined the $\delta^{13}\text{C}$ value of CO_2 in the Martian atmosphere to be $+46 \pm 4\text{‰}$ (Webster et al. 2013). The result was confirmed by an ICP mass spectrometer on-board of the same rover. The ^{13}C -enriched composition of the Martian atmospheric CO_2 has

been linked to a catastrophic early loss of atmospheric gases to space, with a preferential escape of molecules with the lighter isotope, ^{12}C (Webster et al. 2013). The Martian carbonate data and the Martian mantle value represent analyses of the SNC meteorites (Grady et al. 2004; Niles et al. 2010). Sources of data: Lyons et al. (2018), Deines and Wickman (1975), Bézard et al. (1987), Niemann et al. (1998), Messenger et al. (2003), Hashizume et al. (2004), Schidlowski (2001), Deines (2002), Grady et al. (2004), Niles et al. (2010), Rubino et al. (2013), Webster et al. (2013), and Marty et al. (2013).

been linked to a catastrophic early loss of atmospheric gases to space, with a preferential escape of molecules with the lighter isotope, ^{12}C (Webster et al. 2013).

The $\delta^{13}\text{C}$ value of CO_2 in the Venusian atmosphere is poorly known. Bézard et al. (1987) determined spectroscopically a $^{12}\text{C}/^{13}\text{C}$ ratio of 86 ± 12 for CO_2 (Fig. 2). The isotope composition of carbon in CO_2 has also been measured using mass spectrometers carried by planetary probes, but due to analytical problems, these values might be biased (Hoffman et al. 1980; Bézard et al. 1987).

Meteorites

With a few exceptions, the meteorites are thought to have their origin in the asteroid belt between Mars and Jupiter. Among them, chondrites are primitive meteorites, which have not been significantly modified by planet building processes. In chondrites, carbon is mainly present as organic matter, with $\delta^{13}\text{C}$ values ranging from -22.6 to

+14.0‰ in the bulk material (Marty et al. 2013). In the most primitive CI chondrites (standing for carbonaceous chondrite Ivuna, Tanzania), the range of $\delta^{13}\text{C}$ values is smaller, from -14.7 to -4.3 ‰ (Fig. 2). Carbonates in carbonaceous chondrites are highly enriched in ^{13}C , with more than 70% range in $\delta^{13}\text{C}$ values and the highest value of +67.8‰, while organic matter has a smaller range in $\delta^{13}\text{C}$ values from -34.2 to -4.5 ‰ (Marty et al. 2013).

Carbon-bearing phases in iron meteorites have $\delta^{13}\text{C}$ values in the range from -3.9 to -30.3 ‰ (Deines and Wickman 1975). In separate phases, the $\delta^{13}\text{C}$ values fall in the range from -4.8 to -8.2 ‰ for nodular graphite, -18.1 to -19.2 ‰ for cohenite (iron carbide mineral) and -19.7 to -22.1 ‰ for taenite (Fe-Ni alloy) (Deines and Wickman 1975).

SNC Meteorites (Shergottites, Nakhilites, and Chassignites)

Numerous lines of evidence indicate a Martian origin for the SNC meteorites. Their comprehensive analysis has yielded much information about isotope composition of carbon-bearing phases on Mars. Trace carbon associated with primary magmatic rocks (basalts) of SNC meteorites suggests that the $\delta^{13}\text{C}$ value of Martian mantle carbon is -20 ± 4 ‰ (Grady et al. 2004; Fig. 2), implying disequilibrium with the Martian atmosphere.

Most SNC meteorites also contain carbonates, which are characterized by a surprisingly large span of $\delta^{13}\text{C}$ values from -20 to $+65$ ‰ (Niles et al. 2010; Fig. 2). The lowest $\delta^{13}\text{C}$ values are similar in the isotope composition to the Martian mantle carbon, whereas the highest values exceed those measured for the Martian atmosphere, but are similar to the $\delta^{13}\text{C}$ values measured in carbonaceous chondrites (see above). It appears that both the mantle and the atmosphere have been sources of carbon for the Martian carbonates.

Earth

While carbon is the fourth most abundant element in the solar system (after hydrogen, helium, and oxygen), it is fourteenth in abundance in the Earth crust. The mantle and the crust are the most important and relatively well-characterized terrestrial

pools of carbon. The metallic iron core is an additional, poorly characterized reservoir, with the amount of carbon potentially exceeding that in the mantle and crust (Wood et al. 2013; Horita and Polyakov 2015). No samples from the core are available, and therefore, the size and isotopic composition of this reservoir are inferred only on theoretical and experimental arguments.

Mantle carbon has a $\delta^{13}\text{C}$ value of -5 ± 3 ‰ (Deines 2002; Horita and Polyakov 2015). Recent evidence from superdeep diamonds has revealed considerable heterogeneity in the carbon isotope composition of the deep convecting mantle, with the most negative C isotope values typical for diamonds derived from the transition zone or having a subducted oceanic crust origin (Shirey et al. 2013; Burnham et al. 2015). The superdeep diamonds seem to have $\delta^{13}\text{C}$ values spanning the whole range of crustal carbon, which has been interpreted to reflect deep subduction of crustal materials (Shirey et al. 2013; Burnham et al. 2015). Since the efficiency of subduction of carbonate and organic carbon is different under high temperature and pressure conditions (Duncan and Dasgupta 2017), the new observations highlight substantial uncertainty regarding the estimate of the mean $\delta^{13}\text{C}$ value for the mantle carbon.

Crustal carbon, predominantly in sedimentary and metasedimentary rocks, is ultimately derived from the mantle and generally thought to have the same average $\delta^{13}\text{C}$ value of -5 ‰. However, the crust is much more heterogeneous than the mantle in carbon isotope composition, with carbonates having $\delta^{13}\text{C}$ values close to 0‰ (but in rare cases as high as +28‰) and organic carbon/graphite having $\delta^{13}\text{C}$ values close to -30 ‰ (but in rare cases values as low as -70 ‰ have been observed).

Consideration of carbon isotope fractionation between carbon minerals and liquid iron has led to a suggestion that the $\delta^{13}\text{C}$ value of carbon in the core could be significantly lower than that in the mantle (Wood et al. 2013; Horita and Polyakov 2015), possibly in the range from -15 to -10 ‰. It follows then that the generally accepted $\delta^{13}\text{C}$ value for the mantle of -5 ‰ does not necessarily represent the mean isotope composition of all terrestrial carbon.

Early Fractionation of the Solar System Carbon

The carbon isotope data (Fig. 2) provide evidence for a systematic ^{13}C -enrichment in meteorites and terrestrial planets in comparison to the bulk composition of the Solar System. The large-scale difference in the $\delta^{13}\text{C}$ values suggests early fractionation either in the presolar molecular cloud or during the formation of the Solar System. Lyons et al. (2018) argued for inheritance of the variable carbon isotope composition from the molecular cloud where the fractionation was possibly induced by photochemical self-shielding reactions during CO dissociation (Clayton 2002).

Applications

Biogeochemical C Cycle on Earth

Earth is a tectonically active planet, with carbon reservoirs at the surface of the Earth, in the crust,

the mantle, and, possibly, the core. Carbon cycles on different timescales among these reservoirs. Due to associated fractionations and a distinct isotope composition of different reservoirs, carbon isotope studies provide a powerful tool for understanding how the carbon cycle operated in the past and works at the present.

The most significant fractionation in the terrestrial carbon cycle is associated with the photosynthetic assimilation of CO_2 by autotrophic algae and bacteria, strongly favoring the light isotope, ^{12}C (Fig. 3). The amount of fractionation varies according to the carbon-fixation pathway, environmental conditions, and the possible heterotrophic processing of the photosynthetically fixed carbon.

Enzyme-catalyzed fixation of carbon from CO_2 by the *Bacteria* and *Archaea* follows six different cycles/pathways, each with a distinct C isotope fractionation (Berg et al. 2010): (1) reductive pentose phosphate cycle (=Calvin cycle; PP) using

Carbon Isotopes in the Solar System, Fig. 3 Carbon isotope fractionation ($\epsilon_{\text{substrate-biomass}}$) for autotrophic pathways of carbon fixation from CO_2 or HCO_3^- to biomass and for methanotrophic pathways of carbon fixation from CH_4 to biomass according to Zerkle et al. (2005) and Berg et al. (2010). The carbon fixation pathways from CO_2 or HCO_3^- are the reductive pentose phosphate cycle (PP), the acetyl-CoA pathway (AP), the 3-hydroxypropionate cycle (3-HP), the reductive TCA cycle (TCA), the

hydroxypropionate-hydroxybutyrate cycle (HH), and the dicarboxylate- hydroxybutyrate cycle (DH). Also shown is the fractionation associated with the AP pathway forming methane or acetate as a metabolic product (AP-MP). Carbon fixation pathways from methane are bacterial methanotrophy using the RuMP pathway (RuMP), methanotrophy using the Serine Pathway (S), and the anaerobic methanotrophy pathway (AOM)

RubisCO enzyme; (2) reductive acetyl-coenzyme A pathway (=acetyl-CoA) pathway (AP); (3) 3-hydroxypropionate bicycle (3-HP); (4) reductive citric acid cycle (=tricarboxylic acid; TCA); (5) hydroxypropionate-hydroxybutyrate cycle (HH); and (6) dicarboxylate-hydroxybutyrate cycle (DH). Only the first two cycles reach up to 30‰ fractionation, the next two generate up to 12–14‰ fractionation, while the last two produce smaller 0.2–3.8‰ fractionation. The most negative $\delta^{13}\text{C}$ values in the biosphere are associated with the sulfur-oxidizing bacteria using the AP pathway and methanotrophic bacteria (Fig. 3). Importantly, Fig. 3 illustrates that it is difficult, if not impossible, to infer specific metabolic activity from C isotope data alone, although combined with other geochemical and isotopic proxies C isotope data could be informative to fingerprint the ancient community.

Carbon enters the atmosphere-hydrosphere-biosphere system with volcanic gases from the mantle and with the weathering flux from the supracrustal rocks in the continental crust. Both these fluxes are believed to have a $\delta^{13}\text{C}$ value of about -5‰ . Carbon leaves the atmosphere-hydrosphere-biosphere system in the form of sedimentary carbonates and organic matter.

On geologic timescales, a steady state is generally assumed for the carbon cycle. Under these conditions, carbon isotope mass balance can be applied to define the fraction of organic carbon in carbon burial:

$$\delta^{13}\text{C}_i = f_{\text{org}}\delta^{13}\text{C}_{\text{org}} + (1 - f_{\text{org}})\delta^{13}\text{C}_{\text{carb}}, \quad (5)$$

where i refers to the input flux of C, f_{org} to the fractional burial flux of organic carbon, and $\delta^{13}\text{C}_{\text{org}}$ and $\delta^{13}\text{C}_{\text{carb}}$ indicate the isotope composition of carbon buried as organic matter and sedimentary carbonates, respectively.

For most of the geological history, sedimentary carbonates have been characterized by $\delta^{13}\text{C}$ values of $0 \pm 3\text{‰}$, and the isotope composition of sedimentary organic matter has been within the $\delta^{13}\text{C}$ range from -40 to -15‰ , with an average value of about -25‰ (Schidlowski 2001). Applying these values to Eq. 5 gives $f_{\text{org}} = 0.2$ as the organic carbon burial fraction. In the

absence of life, nearly all carbon would have been buried as sedimentary carbonates with a $\delta^{13}\text{C}$ value of -5‰ . This value is not typical even for the oldest preserved sedimentary carbonates, and therefore, the isotope record of sedimentary carbon appears to provide strong evidence for the burial of carbon in isotopically distinct carbonate and organic carbon forms in roughly constant proportion from the time of the oldest preserved sediments at about 3.8 Ga (Schidlowski 2001).

The carbon isotope mass balance model assumes the same isotopic composition for the input fluxes from the mantle and weathering. Isotopic composition of carbon in mantle-derived carbonate melts (carbonatites) and diamonds suggests no secular evolution in the $\delta^{13}\text{C}$ values of mantle-derived carbon over the geological history of the Earth (Deines 2002). However, the $\delta^{13}\text{C}$ values of the weathering flux were not necessarily the same in the Precambrian when atmospheric O_2 levels were lower (Bekker and Holland 2012; Daines et al. 2017). In the present-day oxidizing weathering environments, all organic carbon from the upper continental crust is oxidized to CO_2 , which is then available to biogeochemical carbon cycling in the atmosphere-hydrosphere-biosphere system (Holland 1984). Under low atmospheric O_2 content, a fraction of the sedimentary organic carbon, proportional to the atmospheric $p\text{O}_2$, would be recycled as reduced carbon to sediments, resulting in a higher $\delta^{13}\text{C}$ value of the weathering flux. Therefore, the application of the carbon isotope mass balance model with the above assumptions may be misleading to describe carbon cycling at low atmospheric O_2 conditions, such as those that prevailed during the Precambrian (Bekker and Holland 2012; Daines et al. 2017). In contrast, these considerations ultimately suggest an operation of the biogeochemical carbon cycle at much lower gross primary productivity levels, consistent with independent evidence from multiple oxygen isotope composition of terrestrial and marine sulfates (Crockford et al. 2018).

The isotope composition of all biogenic carbon is depleted in ^{13}C relative to that of inorganic carbon or mantle carbon (Fig. 3). However, the

low $\delta^{13}\text{C}$ values should not be used as unequivocal evidence for biological origin. Primitive meteorites and interstellar dust particles contain organic matter with the lowest $\delta^{13}\text{C}$ values reaching -34.2% in chondrites (considered to be geochemically similar to the bulk Earth) and -15% in CI carbonaceous chondrites (taken to be the most primitive meteorites) (Marty et al. 2013). These values are thought to have been derived from abiogenic exchange reactions in the presolar molecular cloud and the protoplanetary nebula. In addition, various hydrothermal reactions are known to produce reduced carbon with carbon isotope ratios comparable to biogenic organic carbon (e.g., Horita and Berndt 1999; Sherwood Lollar et al. 2006). These reactions include metal-catalyzed Fischer-Tropsch synthesis in high temperature and pressure environments, metamorphic heating of carbonate- or graphite-bearing rocks, and the serpentinization reactions within ultramafic rocks. To establish biogenic origin, carbon isotope values of reduced carbon should be interpreted within its geological framework, such as environmental conditions at the time when it formed, and along with the constrained impact of biogenic activity on the local environment.

Future Directions

Future planetary missions and probes will provide carbon isotope measurements and bring rock samples from planets and asteroids back to Earth. New data will greatly improve our understanding of the processes responsible for the distribution of carbon isotopes in our Solar System, and carbon isotope determinations on minerals, bulk rocks, atmospheric gases, and organic compounds will provide key parameters for the continuing search for extraterrestrial life.

Carbon Monosulfide (CS)

William M. Irvine
Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

CS

Definition

The diatomic molecule carbon monosulfide, CS, is widespread in interstellar and circumstellar ► [molecular clouds](#), in our ► [Milky Way](#) and in external galaxies. Its emission at millimeter

wavelengths is frequently used to estimate the density in these regions, since these pure rotational transitions require densities greater than about 10^5 molecules per cubic centimeter to be excited by collisions. Various isotopic variants have been observed astronomically, including those with ^{13}C , ^{34}S , and ^{33}S , as well as the most abundant $^{12}\text{C}^{32}\text{S}$. CS is also observed in cometary comae.

History

Interstellar CS was first detected by radio astronomers in 1971.

Carbon Monoxide

Thomas McCollom
Laboratory for Atmospheric and Space Physics,
University of Colorado, Boulder, CO, USA

Synonyms

[CO](#)

Definition

Carbon monoxide is a diatomic compound with the chemical composition CO. At terrestrial atmospheric pressure, the melting point of pure

carbon monoxide is $-205\text{ }^{\circ}\text{C}$ and the boiling point is $-191.5\text{ }^{\circ}\text{C}$.

Overview

Carbon monoxide is not known to occur as a pure substance in most planetary environments, but instead occurs primarily as a minor component in gas and ice mixtures. Carbon monoxide is the most abundant constituent after molecular hydrogen in interstellar space (see ► [Molecules in Space](#)), and spectroscopic observations indicate it composes several percent of the icy component of ► [comets](#) (which is predominantly water ice). These observations indicate carbon monoxide was a significant reservoir of carbon during formation of the solar system. In planetary bodies, carbon monoxide primarily occurs as a trace component in atmospheres (~ 0.1 parts per million on the present Earth) and in volcanic gases.

Transformations between carbon monoxide and ► [carbon dioxide](#) (CO_2) proceed fairly readily through photochemical reactions in planetary atmospheres and through mechanisms such as the so-called water-gas shift reaction in geologic environments ($\text{CO} + \text{H}_2\text{O} \leftrightarrow \text{CO}_2 + \text{H}_2$). The latter is an oxidation-reduction reaction, and at the prevailing oxidation state of the Earth's interior, carbon dioxide is strongly favored by chemical thermodynamics relative to carbon monoxide. Consequently, $\text{CO}_2\text{:CO}$ ratios in volcanic gases on Earth are typically in a range of $10^3\text{--}10^5$. Carbon monoxide may also be generated from dehydration of ► [formic acid](#) and vice versa ($\text{HCOOH} \leftrightarrow \text{CO} + \text{H}_2\text{O}$).

Carbon monoxide readily forms complexes with transition metals, such as iron carbonyl [$\text{Fe}(\text{CO})_5$] (carbonyl is the name given to the CO radical). Formation of carbonyls from carbon monoxide can also occur on the surface of transition metal-bearing minerals and alloys. Carbonyls are highly reactive, and carbonyls derived from carbon monoxide have been hypothesized to be a key reactant for the in situ formation of prebiotic organic compounds in several scenarios for the ► [origin of life](#) (e.g., Huber and Wächtershäuser 1997). One such reaction that is frequently

invoked for the formation of organic matter in the early solar system is Fischer-Tropsch synthesis, a surface-catalyzed process for conversion of gaseous mixtures of CO and H₂ to hydrocarbons and other functionalized organic compounds such as fatty acids. Potential environments for the surface-catalyzed conversion of carbon monoxide to prebiotic organic compounds by the Fischer-Tropsch synthesis or other processes include dust grains in the early solar system, volcanic fumaroles, and hydrothermal systems.

Carbon Source

Felipe Gomez
Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

Carbon source refers to any carbon-containing molecule (carbohydrate, amino acid, fatty acid, CO₂)

used by an organism for the synthesis of its organic molecules. Carbon is a basic element for sustaining life as we know it and the main element in all classes of macromolecules. All cells require carbon as a major nutrient. On a dry weight basis, a typical cell is 50% carbon. Depending on their carbon source, organisms are either heterotrophs, requiring one or more organic compounds as their carbon source, or autotrophs, where CO₂ is the carbon source.

Definition

Carbonaceous Chondrites (CCs) are stony fragments of primitive asteroids that never became

hot enough to melt and differentiate. As such, they preserve with varying degrees of fidelity a record of the dust present in the solar protoplanetary disk when and where they formed. CCs have varying but near solar nonvolatile chemical compositions and contain carbon in the range 0–4 weight percent (wt. %) as well as water/OH (0–13 wt.% in hydrated minerals) and all other biogenic elements (e.g., nitrogen, phosphorous, sulfur). Most of the CC carbon is in organic materials that include both kerogen-like insoluble macromolecular materials and soluble organic compounds, such as amino acids. The macromolecular materials dominate, but the relative proportions of the organic components change within and between groups. Meteorites are generally categorized as falls or finds depending on whether their falls to Earth were observed or not. Falls are more desirable for organic analyses since they have been less exposed to terrestrial contamination. Nevertheless, both Japanese and American institutions have established programs that search for meteorite finds in Antarctica because the cold temperatures and their storage in the ice means that they can remain relatively pristine for long periods of time. Based on their physical, chemical, and isotopic properties, the CCs have, so far, been subdivided into eight recognized groups: CI, CM, CR, CK, CH, CB, CO, and CV, where the second letter generally refers to the type meteorite for a group (Ivuna, Mighei, Renazzo, Karoonda, High metal, Bencubbin, Ornans, and Vigarano, respectively). The separate groups are probably fragments from different parent asteroids. Some CCs, such as the recent falls Tagish Lake and Sutters' Mill, have features that are distinct from any of these groups, are simply classified as C ungrouped, and probably come from less well sampled asteroids.

Overview

The CCs are stony meteorites whose bulk non-volatile elemental compositions are to varying degrees similar to that of the Sun. All the CCs experienced at least some degree of aqueous

alteration and/or thermal metamorphism in their parent asteroids that modified or even destroyed the organic materials they originally contained. The least heated CCs contain abundant carbon (~1–4 wt.%, depending on the group) that is mostly in organic materials. This organic material, which is classified procedurally as either solvent soluble organic material (SOM) or insoluble organic material (IOM), provides a record of organic chemistry in the early Solar System at about the time the Earth was forming and before the inception of terrestrial life (Alexander et al. 2017; Glavin et al. 2018).

High-resolution mass spectroscopy indicates that some CCs contain at least tens of thousands of individual soluble compounds, and those identified to date include: water-soluble carboxylic-, dicarboxylic-, amino-, hydroxy-, keto-, and pyridine carboxylic-acids; sugar alcohols and acids, aldehydes and ketones; amines and amides; purine bases and pyrimidine bases; and solvents-soluble aliphatic, aromatic, and heteroatom containing hydrocarbons. Many CC compounds have counterparts in the biosphere, for example, 12 detected amino acids are also found in terrestrial proteins: *glycine*, *alanine*, *proline*, *valine*, *leucine*, *isoleucine*, *serine*, *threonine*, *tyrosine*, *phenylalanine*, *aspartic-*, and *glutamic acids*.

Another similarity between terrestrial and meteoritic amino acids is their chirality and the occurrence in some of L-enantiomeric excesses (Glavin et al. 2020). To date, this chiral asymmetry has only been found in a few CC amino acids, is not constant even for the same amino acid in different members of the same group, and is of unknown origin. Nevertheless, it shows the presence in abiotic environments of possible chiral influences and enhances the astrobiological significance of meteoritic compounds. Contrary to the compositional selectivity and homochirality of biomolecules, however, most meteoritic compounds do not show chiral preferences and are found with almost complete structural diversity for a given carbon number, for example, close to 100 amino acids have been identified to date in meteorites compared to the 23 that are the

constituents of terrestrial proteins (Pizzarello and Shock 2010).

The IOM is in bulk a structurally complex, macromolecular material with an elemental composition in the least heated samples of $\sim\text{C}_{100}\text{H}_{79}\text{N}_4\text{O}_{15}\text{S}_3$, which is similar to the averages of the refractory organic materials in the dust from comets Halley and 67P/Churyumov-Gerasimenko (Alexander et al. 2017; Isnard et al. 2019). Degradative, pyrolytic, and spectroscopic studies all point to the IOM being composed of small aromatic units that are linked by short, highly branched aliphatic chains. In situ observations show that the IOM is dispersed in chondrite matrices as chemically and isotopically diverse particles that are typically $<1\text{ }\mu\text{m}$ across. There are no apparent physical/spatial associations between the IOM particles and any minerals that could, for instance, have played a role in their formation.

Although the origins of the CC soluble and insoluble materials have yet to be established, both are likely to be the products of long cosmic histories. Their isotopic compositions show enrichments in ^2H (deuterium) and ^{15}N that point to the synthesis of the organic materials or their precursors in very cold, radiation-rich environments such as would have been found in the protosolar molecular cloud and the outer solar protoplanetary disk. Once in the CC asteroidal parent bodies, internal heating by the decay of short-lived radionuclides and impacts drove the melting of ices and alteration processes akin to low-temperature serpentinization on Earth. While not well understood, the presence of aqueous fluids almost certainly resulted in the modification of the original soluble organic inventories (e.g., formation of amino acids by Strecker synthesis and Michael addition). Experiments and observations from meteorites indicate that the IOM would also have been chemically and isotopically modified during this period of aqueous activity, including the release of water- and solvents-soluble compounds (e.g., Yabuta et al. 2007). In many CCs, further heating led to their progressive dehydration, recrystallization, and destruction of their organic materials.

Carbonate on Mars

Nicholas Arndt

Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Synonyms

[Calcareous sediment](#); [Limestone](#)

Definition

The term carbonate refers either to a mineral or to a rock. Examples of carbonate minerals are:

1. Calcite (CaCO_3) and dolomite ($\text{MgCa}(\text{CO}_3)_2$), which are common constituents of limestones and other calcareous sediments
2. Siderite (FeCO_3), which also occurs in ► [sedimentary rocks](#)
3. Magnesite (MgCO_3), an alteration product of ultramafic rock
4. Malachite $\text{Cu}_2(\text{CO}_3)(\text{OH})_2$, smithsonite (ZnCO_3), rhodocrosite (MnCO_3), withérite (BaCO_3), and cerussite (PbCO_3), which result from surficial alteration of metallic ore deposits.

The term “carbonate” is also applied to sediments or ► [sedimentary rocks](#) such as limestones or dolostones that are composed predominantly of carbonate minerals. In the Precambrian, particularly the Proterozoic, carbonate minerals precipitated on microbial mats by their photosynthetic activity and resulting alkalinity of the surface are common. Most

Phanerozoic carbonates are composed to a large degree of the shells, tests, and spicules or their fragments of marine organisms, cemented by secondary carbonates. Rarely, carbonates precipitate chemically directly from sea- or lake water. Dolomite, a widespread carbonate, has variable origins, but its precipitation is also known to be biologically mediated. Carbonate sediments are rare in Archean sequences but common as cements. Recent studies on Mars dust, performed by Martian rovers, showed that the dominant carbonate mineral is magnesite; which may provide evidence for the presence of water at the surface early in the history of [▶ Mars](#).

Carbonate, Extraterrestrial

Daniela Tirsch
German Aerospace Center DLR, Institute of
Planetary Research, Berlin, Germany

Definition

The term carbonate can either refer to carbonate minerals, which contain the carbonate ion CO_3^{2-} , or to carbonate rocks, which contain carbonate minerals. On Earth, the vast majority of carbonate rocks are of sedimentary origin, while igneous carbonates (carbonatites) are extremely rare. Furthermore, the formation of carbonate minerals on Earth generally takes place within an aqueous solution, either through abiotic precipitation or biomineralization. Hence, the presence of carbonates on other planets (especially Mars) is viewed as an indicator for the former presence of liquid water. Extraterrestrial carbonates have been identified in a wide range of localities on Mars as well as in several Martian meteorites. They include magnesium carbonate detections in the Nili Fossae region, carbonates intermixed with iron/magnesium-smectites (phyllosilicates) in the Libya Montes

region, magnesium-rich carbonates at Gusev crater, and calcium-/iron-rich carbonates at various spots in Tyrrenia Terra. The spectral signatures share similarities with carbonaceous chondrites.

 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

In organic chemistry, a carbonyl is a functional group consisting of a carbon atom doubly bonded to an oxygen atom (Fig. 1). Some examples of carbonyl-group-containing compounds include carboxylic acids and their derivatives (e.g., amides, esters, and anhydrides), aldehydes, and ketones. The term carbonyl can also refer to a ligand in an organometallic complex (e.g., iron pentacarbonyl, $\text{Fe}(\text{CO})_5$).

Since oxygen is more electronegative than carbon, the oxygen atom in a carbonyl group pulls electron density toward itself and away from carbon, making the bond polar. The carbonyl carbon thus tends to be electrophilic and more reactive with nucleophiles. The electronegative oxygen can react with an electrophile.

Protons bonded to carbon atoms alpha to a carbonyl group are often considerably more acidic (by $<3pK_a$ units) than typical aliphatic C-H bonded protons. The carbonyl group is in tautomeric equilibrium with an enol configuration. Deprotonation of this enol produces an enolate anion, which is nucleophilic, and can alkylate electrophiles such as other carbonyls.

Definition

In chemistry, carboxylic acids are organic acids that contain a carboxyl functional group. The general formula of a carboxylic acid is R-COOH . Carboxylic acids are proton donors. Some common examples are ► [formic acid](#), H-COOH , and ► [acetic acid](#), CH_3COOH . There are many carboxylic acids of biological importance, for example, fatty acid esters are important components of many cell membranes, proteins are polymers of amino acids, and many compounds in intermediary metabolism are carboxylic acids. Common prebiotic syntheses of carboxylic acids proceed via the hydrolysis of precursor nitriles.

Because they are both hydrogen-bond acceptors and hydrogen-bond donors, they are able to participate in hydrogen bonding. Carboxylic acids tend to have higher boiling points than water, partly because of their tendency to form hydrogen-bonded dimers. Carboxylic acids are polar: short-chain aliphatic carboxylic acids (e.g., those containing one to five carbon atoms) are soluble in water, whereas higher carboxylic acids are less soluble due to the increasingly hydrophobic nature of their aliphatic components.

Carboxylic acids form various derivatives in combination with other functional group-containing compounds, for example, esters in combination with alcohols, amides in combination with amines, and anhydrides in combination with another carboxylic acid.

Keywords

Carbonyl · Fatty acids · Hydroxyl · Organic acid · Carboxyl · Lipids

Synonyms

[Fatty acids](#)

Definition

► [Carboxylic acids](#) are a class of organic compounds that contain one or more carboxyl groups per molecule. Each carboxyl group, which is a combination of ► [carbonyl](#) and hydroxyl groups, has the formula -C(=O)OH (or -COOH). Carboxylic acids are polar and proton donors. Carboxylic acids are widespread in nature, often combined with other functional groups, and ubiquitous in biology, recent sediments, and carbonaceous meteorites. As they degrade during diagenesis and thermal maturation in the rock record, they generally transform into esters, carboxylates (i.e., hydroxyl group replaced with salts or anions), and, eventually, alkanes.

Overview

Carboxyl groups are polar. The carbonyl group is a hydrogen-bond acceptor, and the hydroxyl group is a hydrogen-bond donor. Consequently, carboxylic acids participate in hydrogen bonding, particularly with each other and with minerals such as phyllosilicates, oxyhydroxides, and other oxides. In addition, the “self-association” of carboxylic acids that results from hydrogen bonding generates stabilized dimeric pairs in nonpolar media. The dimers have decreased volatility. The bonds must be broken chemically or thermally for the carboxyl group to be reactive to other geochemicals. The stabilization of dimers and the nonreactive nature of the alkyl side chain (or other carbon skeleton) contribute to the refractory nature of carboxylic acids during diagenesis compared to more polar organic molecules.

Carboxylic acids having more than five carbons in an alkyl chain are not soluble in water unless at high temperatures and exhibit both hydrophilic (carboxyl) and hydrophobic (alkyl) regions in the same molecule. The amphiphilic nature of these molecules leads to the formation of nonbiological monolayers on the water and mineral surfaces or micelles, sphere-shaped clusters, in solution. Biology takes advantage of the amphiphilic nature of carboxylic acids to form fatty acid lipid bilayers of

cellular ► [membranes](#). Formation of nonbiological monolayers was likely critical for the formation of the earliest cellular life.

Carboxylic acids are weak acids that only partially dissociate into H⁺ cations and RCOO⁻ anions in pH neutral aqueous solution. In the presence of a base, carboxylic acids become carboxylates. These moieties are important in geological and biogeochemical processes because they can be siderophores, chelating with metals, such as ferric iron.

The carbon atom of a carboxyl group is in a relatively high ► [oxidation](#) state and can be partially reduced by sulfur or other organic molecules during diagenesis under reducing conditions. ► [Oxidation](#) of the carboxyl carbon commonly occurs in oxidizing environments to form carbon dioxide (decarboxylation reaction). Depending on the geochemical or biological reaction, the alkyl side chain may end up reduced to an alkane or oxidized, often with the addition of an anion or salt. In both cases, decarboxylation results in the loss of a carbon from the carbon skeleton, and the product can then be preserved in the rock record. Consequently, a series of carboxylic acids preserved in a geological record is often associated with a corresponding series of alkanes with one less carbon.

Definition

Carboxysomes are intracellular proteinaceous compartments found in cyanobacteria and some ► [chemoautotrophs](#) that encapsulate the enzymes carbonic anhydrase and ribulose-1,5-bisphosphate carboxylase/oxygenase (► [RuBisCO](#)). The function of the carboxysome is to concentrate CO₂ with close proximity to RuBisCO, eliminating the competitive reaction with oxygen. Thus, carboxysomes are the site of carbon dioxide (CO₂) fixation.

History

In 1956 the first carboxysomes (then termed polyhedral bodies) were visualized in a cyanobacterium

(Drews and Niklowitz 1956). Following the discovery of similar structures in several other cyanobacteria and chemoautotrophs, carboxysomes were purified in 1973 and shown to contain the enzyme, ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) (Shively et al. 1973). Because RuBisCO plays a central role in carbon fixation, they were given the name carboxysomes.

Overview

Carboxysomes are intracellular organelles composed of a proteinaceous shell that encapsulates the enzyme carbonic anhydrase and ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) (Cameron et al. 2013). Unlike other types of organelles, no lipids are associated with carboxysomes. Carboxysomes are icosahedral in shape, akin to bacterial phages and capsid viruses. However, there is no other evidence of an evolutionary connection between carboxysomes and any known viruses.

X-ray crystallography of individual shell proteins revealed hexamers as the basic micro-compartment shell structure building block and showed how these hexamers assemble to form the walls of polyhedral shell (Kerfeld et al. 2005). Subsequent structural studies determined that another universally conserved shell protein forms pentameric structures that are located in the vertices of the icosahedra (Tanaka et al. 2008). These structural studies have led to beautiful structural models of carboxysomes that suggest mechanisms for the passage of molecules through the pores formed by hexameric and pentameric structures (Yeates et al. 2008).

Carboxysomes fall under the broader class of structures, the bacterial microcompartments, which encompasses several functional types. Bacterial microcompartments share evolutionarily related shell proteins which encapsulate different enzymes. Other types of bacterial microcompartments have been shown to utilize 1,2-propanediol, ethanolamine, and choline (Abdul-Rahman et al. 2013).

Carboxysomes are the site of carbon dioxide (CO₂) fixation. Bicarbonate (HCO₃[−]) is

transported into the shell through nanopores, where the shell-associated enzyme, carbonic anhydrase, converts HCO₃[−] to CO₂. RuBisCO packed inside the carboxysome converts the substrates CO₂ and ribulose-1,5-bisphosphate into two 3-phospho-D-glycerate (3-PG) molecules. 3-PG then exits the carboxysome and can be used as a metabolic intermediate in the Calvin-Benson-Bassham cycle.

RuBisCO has low affinity for CO₂ and is capable of binding O₂. The oxygenation of ribulose-1,5-bisphosphate produces phosphoglycolate which can accumulate to toxic levels and inhibit photosynthesis (Yeates et al. 2008). Thus, the shell serves to both concentrate CO₂ around RuBisCO and block oxygen from enzymatically competing with CO₂.

Two types of carboxysomes have been characterized, the α - and β - carboxysomes, named for the form of RuBisCO they encapsulate. The β -carboxysome is found exclusively in cyanobacteria, while the α -carboxysome is found in marine cyanobacteria as well as in some autotrophic [proteobacteria](#). The carboxysome's presence in all cyanobacteria, with the exception of *Cyanobacterium UCYN-A* which lacks genes for carboxysomes and the Calvin cycle (Tripp et al. 2009), indicates it is an essential structure for CO₂ fixation in the phylum.

The great oxidation event (~2.4 billion years ago) altered the atmosphere with the appearance of free atmospheric oxygen and is attributed to the emergence of photosynthetic cyanobacteria that release oxygen as a by-product (Session et al. 2009). Cyanobacterial mutants that lack one or more shell proteins cannot survive under normal atmospheric CO₂ levels and can only grow in high (5%) CO₂ (Ogawa et al. 1994). The ability of cyanobacteria to grow without carboxysome shells at higher CO₂ concentrations suggests that these structures would not be required if the atmosphere's current makeup had higher CO₂ levels.

CASA*, Poland

Franco Ferrari and Ewa Szuszkiewicz
CASA*, Faculty of Mathematics and Physics,
University of Szczecin, Szczecin, Poland

Synonyms

[Centre for Advanced Studies in Astrobiology and Related Topics \(CASA*\)](#)

Definition

The center is structured as a consortium of laboratories based in Poland and coordinated by CASA*. The consortium consists of five founding institutions. Three institutions are in Warsaw: the Space Research Centre, the Nicolaus Copernicus Astronomical Centre, and the Institute of Paleobiology of the Polish Academy of Sciences. The fourth institution is the Nicolaus Copernicus University in Toruń. Finally, the headquarters of CASA* are at the University of Szczecin.

The scopes of CASA* are:

1. To stimulate and promote the research in astrobiology and related topics in Poland
2. To conduct and coordinate interdisciplinary research projects at the Polish level
3. To promote the cooperation of Polish groups working in astrobiology with the other countries of the European Union and in particular to establish a Polish contact point with the *European Space Agency* (ESA) and the *European Astrobiology Network Association* (EANA), which is the main reference for astrobiologists in the European Union
4. To establish a center of excellence in astrobiology research and related topics in Central Europe
5. To start courses in astrobiology in Poland

The research carried out by the teams participating in CASA* covers most of the disciplines of astrobiology including astronomy, astrophysics, astrochemistry, physics, genetics, space medicine, ► [radiation biology](#), microbiology, biogeology, biosedimentology, and ► [geomicrobiology](#). CASA* makes available for its members computing facilities and the structures of the Laboratory for Polymer Research of the University of Szczecin. CASA* is participating in EANA and in the Committee on Space Research of the Polish Academy of Sciences. The center has also representatives in several COST Actions of the European Union and in a number of international projects.

History

Originally CASA* has been founded in 2003 as a virtual center (Szuszkiewicz 2004). It is organized as a consortium since 2007.

The members of CASA* have been active in organizing courses and conferences for students and young researchers in Poland and have participated in the activities of the Astrobiology Lecture Course Network (ABC-Net) supported by ESA. The teaching activity has resulted in the publication of the first book in astrobiology written in Polish entitled *Astrobiology: From cosmic dust to DNA*, published by the Szczecin University Press (Ferrari and Szuszkiewicz 2006).

Cassini

Therese Encrenaz
Observatoire de Paris – Section de Meudon,
LESIA, Meudon, France

Definition

Giovanni Domenico Cassini (or Jean-Dominique Cassini) (1625–1712) was born in Perinaldo, near

Naples, and was Professor at Bologna. In 1669, he became a member of the French Académie des Sciences, and in 1671, he became the first Director of the Observatoire de Paris, from which the Paris Meridian was defined. Its first scientific aims were metrology, celestial mechanics, and positional astrometry. Cassini made important discoveries regarding solar-system objects: determination of Mars' rotation, Jupiter's rotation, Jupiter's satellites' revolutions, identification of several of Saturn's satellites (Iapetus, Rhea, Thetys, and Dione), as well as the Cassini Division within Saturn's rings. Cassini also recorded observations of the ► [zodiacal light](#). The Cassini space mission, launched in 1997 and in operation in the ► [Saturn](#) system between 2005 and 2017, was named after him.

Definition

The Cassini Division is a gap between the A and B rings of ► [Saturn](#). It was first identified by Giovanni Domenico ► [Cassini](#) in 1675 and can be observed with a small telescope. It extends between 117,500 and 122,000 km from the center of Saturn. Observations by the Cassini orbiter have shown that the Cassini division is not devoid of matter, as previously thought, but it consists of a region where the density of particles is lower than that in the main rings themselves. The existence of the Cassini division is probably due to a gravitational interaction with ► [Mimas](#), as the Cassini division is in resonance with the orbit of this satellite. There are other divisions in Saturn rings (Encke division, Keeler division).

Cassini State

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

When an orbiting body is affected by tides, its spin axis, spin rate, and orbital plane can reach an equilibrium state in which obliquities (tilts) are nonzero. Cassini states are observed in the Earth-Moon system, Triton-Neptune system, and possibly, Europa-Jupiter system. In these cases, the satellite's obliquity is locked at a small nonzero value, but in general, with large inclinations, the obliquity could be large.

History

Cassini, Giovanni Domenico [Jean-Dominique] (1625–1712) was an Italian astronomer born in Perinaldo in June 8, 1625. In 1669, Cassini set out for Paris (in 1673, became a naturalized Frenchman) where he will be appointed the first director of the Observatory of Paris, starting that way a family dynasty of prominent astronomers in prerevolutionary France. His astronomical works ranged from studies of comets (that he considered analogous to planets but traveling in paths of greater eccentricity) to the movements of Jupiter's moons and Saturn's satellites and ring. Cassini found the Saturnian satellites, Iapetus (1671), Rhea (1672), and Tethys and Dione (1684) and noted the division of the rings of Saturn.

In 1997 in a joint effort between NASA, ESA, and ASI, the Cassini Mission was launched to study the structure and physical properties and dynamics of Saturn and its satellites, mainly Titan.

Definition

Cassini-Huygens is a large ► NASA-ESA- ► ASI mission, composed of the ► Saturn orbiter (► Cassini) and the ► Titan lander (► Huygens). Cassini-Huygens reached Saturn in 2004 after a trip that lasted about 7.5 years and has since then been investigating the Saturnian environment, carrying out the first detailed survey of the ► planet, its rings, and the 62 currently known satellites, with a focus on ► Titan. The Cassini instruments have returned a great amount of data that have revolutionized our view of the Saturnian system. The orbiter is foreseen to remain operational until 2017.

History

An ambitious and international mission to explore the Saturnian system was initially proposed to the National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA) in 1982 by a team of European and US scientists. After extensive discussions between ESA and NASA, the initial concepts eventually evolved by 1989 into Cassini-Huygens, a mission composed of an American orbiter and a European descent probe. This made it the first truly international planetary mission, in addition to its other unique features. The Italian Space Agency (ASI) is responsible for the spacecraft's radio antenna and portions of three scientific instruments. Cassini-Huygens arrived in the Saturnian system in July 2004. The Huygens probe executed its mission in January 2005. After two extensions, the Cassini orbiter continues its exploration of the Saturnian system until 2017. For a thorough overview of the mission and its objectives, see "The Cassini-Huygens Mission" (Russell 2004).

Overview

Trajectory and Operations

The Cassini-Huygens mission is a fruitful collaboration between ESA, NASA, and ASI which has been investigating the Saturnian system since 2004, bringing spectacular new insights on the primary planet, its rings, and the exchanges within the system and within the Solar System. Particular attention was devoted to the natural satellites, of which Titan, the largest moon, is a special target. The mission has thus been instrumental in enhancing our understanding of the environment around Saturn, in particular as to the habitability potential in bodies around giant planets.

The Cassini-Huygens spacecraft consists of two main elements: the NASA Cassini orbiter, named after the Italian-French astronomer Giovanni Domenico Cassini, who gave his name to the ► Cassini Division in the rings and discovered several of Saturn's major satellites, and the ESA-provided Huygens probe, named after the Dutch astronomer, mathematician, and physicist Christian Huygens, who discovered Titan in 1655. The Cassini-Huygens mission was launched on October 15, 1997, on a Titan IV-Centaur rocket from Cape Canaveral and performed flybys of ► Venus, ► Earth, and ► Jupiter before entering into orbit around Saturn on July 1, 2004 (Fig. 1).

One particular target of Cassini-Huygens was Titan, also visited in situ by the ► Huygens probe: on December 25, 2004, the Huygens probe separated from the orbiter and reached Titan on January 14, 2005, when it descended through the atmosphere, landed on the moon's surface, and relayed scientific information for a total of more than 5 h (Lebreton et al. 2008). Mission control activities for Cassini are conducted from the Space Flight Operations Facility at the Jet Propulsion Laboratory (► JPL), where the project is headquartered.

The Spacecraft and Its Payload

The spacecraft, including the orbiter and the probe, is the largest and most complex interplanetary spacecraft built to date. The orbiter

Cassini-Huygens Space

Mission, Fig. 1 The trajectory of the Cassini-Huygens mission from launch to Saturn orbit insertion

Cassini-Huygens Space

Mission, Fig. 2 Diagram of the Cassini spacecraft carrying the Huygens probe

has a mass of 2,150 kg (plus fuel), and the probe has a mass of 350 kg. The Cassini spacecraft is more than 6.8 m high and more than 4 m wide (Fig. 2). The complexity and mass of the spacecraft is warranted by the ambitious program of scientific observations the spacecraft is performing. Due to this, the spacecraft was not injected into a direct trajectory to Saturn but made use of gravity-assisted maneuvers at Venus, Earth, and Jupiter. These maneuvers increased the duration of the voyage, which lasted about 7.5 years, but at the same time allowed to test the instruments during the different flybys, to improve their calibration, and also to make some interesting

observations at Jupiter in conjunction with the ► [Galileo mission](#) in orbit around the gas giant in December 2000. This brief conjunction of the two probes, complemented by simultaneous observations from the Earth-orbiting Hubble Space Telescope and Chandra X-ray Observatory, provided an unprecedented opportunity for the intimate study of the Solar System's largest planet and enhanced our understanding of Jupiter's radio emission and aurorae and their interaction with the solar wind. Jupiter's magnetosphere and radiation belts and the interactions between the magnetosphere and ► [Io](#), ► [Ganymede](#), and ► [Europa](#) were also explored.

The main body of the orbiter is nearly cylindrical and consists of a lower equipment platform, a propulsion module, and an upper equipment platform, topped by a 4-m diameter high-gain antenna. Attached about halfway up the trunk is a remote sensing pallet, which hosts cameras and other remote sensing instruments, and a fields and particles pallet, which carries instruments that study magnetic fields and charged particles. In order to point the instruments in the correct observing direction, the entire spacecraft must be turned, although three of the instruments possess their own single-axis articulation capability.

Cassini's orbiter instrumentation (Fig. 2) consists of a synthetic-aperture RADAR mapper, a charge-coupled device ► **imaging** system, a visible/infrared mapping spectrometer, a composite infrared spectrometer, a cosmic dust analyzer, a radio and plasma wave experiment, a plasma spectrometer, an ultraviolet imaging spectrograph, a magnetospheric imaging instrument, a magnetometer, and an ion/neutral mass spectrometer. Telemetry from the communications antenna and other special transmitters is also used to make observations of the atmospheres of Titan and Saturn and to measure the gravity fields of the planet and its satellites. On its orbit around Saturn, Cassini finds itself between 8.2 and 10.2 astronomical units (AU) from the Earth. Because of this, it takes between 68 and 84 min for radio signals to travel from Earth to the spacecraft, and vice versa.

More details and updates on the Cassini-Huygens mission can be found at <http://saturn.jpl.nasa.gov/>; <http://sci.esa.int/cassini-huygens/>; http://www.nasa.gov/mission_pages/cassini/main/.

Major Discoveries

The Cassini-Huygens mission has brought a host of new and exciting discoveries in the Saturnian system (Coustenis and Taylor 2008; Lorenz and Mitton 2008; Brown et al. 2009; Dougherty et al. 2009). They concern the distribution and composition of the rings, the nature of the kronian satellites and their interactions with the system, the planet's atmospheric envelope, and its ► **magnetosphere**. But also, the Cassini-Huygens discoveries have completely revolutionized our

perception of the astrobiological and habitable potential in a giant planet system, with strong implications also for exoplanetary worlds.

Given the long duration of the mission, the complexity of the payload onboard the Cassini Orbiter, and the amount of data gathered on the primary planet, the satellites, and rings, it would be impossible to describe all the new discoveries made (the reader can find detailed reviews in the books edited by Dougherty et al. 2009; Brown et al. 2009). We will therefore cite here only a few of the major breakthroughs showing how Cassini's data have opened up a whole new chapter in Solar System exploration and in particular have contributed to our understanding of the astrobiological aspects of many of the Saturnian bodies (Lunine and Raulin 2010; Coustenis and Encrenaz 2013).

In studying the primary planet, Cassini found lightning on Saturn whose power is said to be approximately 1,000 times that of lightning on Earth (Dougherty et al. 2009). In addition, in October 2006, the probe detected an 8,000 km diameter hurricane with a six-sided eyewall at Saturn's South Pole (Fig. 3). The storm's eye is

Cassini-Huygens Space Mission, Fig. 3 This Cassini image shows a large hurricane-like storm at Saturn's south pole. The dark eye of the "hurricane" spans about 8,000 km and it is surrounded by rings of clouds that tower about 30–75 km above it. Contrary to the Earth, Saturn's storm is fixed in place – above the South Pole – and is not powered by an ocean, since Saturn is a gaseous planet

about 2,000 km across with cloud speeds as fast as 530 kph. Scientists believe that the storm is the strongest of its kind ever seen. This observation is particularly notable because eyewall clouds had not previously been seen on any planet other than Earth. In addition, in counterpart, a strong six-sided jet stream was found at Saturn's north pole known as "the hexagon" and photographed again recently to span 32,000 km.

Saturn is probably best known for its system of ► **planetary rings**, which makes it the most visually remarkable object in the solar system. They extend from 6,630 to 120,700 km above Saturn's equator, average approximately 20 m in thickness, and are composed of 93% ► **water** ice with a smattering of ► **tholin** impurities and 7% ► **amorphous carbon**. The particles that make up the rings greatly vary in size. On September 20, 2006, a Cassini photograph revealed a previously undiscovered planetary ring, outside the brighter main rings of Saturn and inside the G and E rings. Apparently, the source of this F ring is the result of the crashing of a meteoroid off two of the moons of Saturn (Dougherty et al. 2009). Indeed, the interactions and material exchange between the rings and the satellites provide a significant

breakthrough in our understanding of the Saturnian system provided by the Cassini spacecraft (Fig. 4). Thus, on October 6, 2009, another discovery was announced of a tenuous outer disk of material in the plane of ► **Phoebe's** orbit. The ring is from 128 to 207 times the radius of Saturn and is thought to originate from micrometeoroid impacts on the satellite Phoebe, which orbits at an average distance of 215 Saturn radii. The ring material should thus share Phoebe's retrograde orbital motion and after migrating inward would encounter ► **Iapetus'** leading face, which could help explain the dramatic two-faced nature of this satellite. While the infalling material cannot be directly responsible for the observed pattern of light and dark regions on Iapetus, it is believed to have initiated a runaway thermal self-segregation process in which ice sublimates from warmer regions and condenses onto cooler regions. This leaves contrasting areas of dark ice-depleted residue and bright ice deposits. Another important discovery was that the source of the material in the E ring, the second outermost and very wide, was probably the water-laden plumes emanating from the "tiger stripes" of the south polar region of the cryovolcanic satellite

Cassini-Huygens Space Mission, Fig. 4 Cassini captures the effects of the small moon Prometheus on two of Saturn's rings in this image taken on July 30, 2009, at a distance of approximately 1.8 million kilometers from Saturn. A long, thin shadow cast by the moon stretches across the A ring on the right. The gravity of the small

moon Prometheus periodically creates streamer-channels in the F ring, as can be seen on the left of the image. Prometheus is overexposed in this image. Bright specks in the image are background stars. This view looks toward the northern, dark side of the rings from about 28° above the ring plane

Enceladus. Besides the main Cassini division, other gaps have been found in the rings where particle density drops significantly. A couple of them have identified origins by known moons embedded within them, while others are at locations of known ► [orbital resonances](#) with ► [Saturn](#)'s other moons. Finally, still some gaps remain unexplained to date.

So far, the mission has discovered and confirmed several new satellites, bringing the number up to 62. In the satellite system, the Cassini orbiter has produced a large range of new results, demonstrating that these small bodies are far from being icy, dead worlds but rather active bodies with resurfacing and cryovolcanic features. The moons of Saturn are a diverse collection (Fig. 5). Cassini has explored their icy landscapes in unprecedented detail, solving long-standing mysteries and sharing many new surprises: ► [Iapetus](#) has an enormous ridge along its equator, in addition to its two sides of remarkably different

brightness. ► [Rhea](#) may have its own faint rings. And sponge-looking Hyperion is so porous that impacts tend to just punch into the surface, and its gravity is so low that what material does get ejected tends to leave the moon altogether.

A big surprise came from February 2010 observations of ► [Mimas](#), the satellite characterized by the 130-km wide Herschel crater dominating its surface, showing large temperature differences across the surface with no surface brightness features to explain it. The differences are believed to be due to Mimas' thermal inertia being considerably higher in the colder regions than the hotter. In such a case, heat could soak into the Mimas interior more easily, rather than raise the temperature of the surface. This supposes that the thermal conductivity of the satellite has to be at least ten times greater in the cold regions with respect to the warmer regions, while there are no apparent differences in the visible-wavelength observations. These facts and the giant crater,

Cassini-Huygens Space Mission, Fig. 5 On June 28, 2007, the Cassini cameras captured this trio of icy moons against Saturn's atmosphere and rings (Dougherty et al. 2009). Enceladus is located on the planet's shadow-draped limb at the center; Pandora is a bright speck hovering near the rings; and Mimas is seen at lower right. The

view was obtained at a distance of approximately 291,000 km from Enceladus, looking toward the sunlit side of the rings from about a degree below the ringplane. Scale in the image ranges from 17 km per pixel on Enceladus to 32 km per pixel on Saturn in the background

Herschel, residing within this cold region remain a mystery.

Cassini also discovered the presence of organics (hydrocarbons mainly) on several of Saturn's satellites seen through their signatures in several of the instruments' data, not only on Titan and ► [Enceladus](#), but also on Iapetus and Phoebe and ► [Dione](#), with Cassini VIMS showing that the dark material in the Saturn system could be organics (Dougherty et al. 2009).

More surprises came from the combined investigations of the orbiter and of the Huygens probe in the case of Titan as shown for example in Fig. 6 for the Huygens landing site (Coustenis and Taylor 2008; Lorenz and Mitton 2008; Mueller-Wodarg et al. 2014) but also from very close Cassini flybys of Enceladus (Brown et al. 2009). In some ways, the moons Titan and Enceladus have turned out to be unique revelations of the Cassini mission, making the Saturnian system's exploration very relevant to the search for ► [life](#) and habitable conditions in the Solar System. Titan, with its thick organic-laden atmosphere, clouds, dunes, and rivers and lakes of liquid ► [methane](#)-ethane on its surface (Stofan et al. 2007; Brown et al. 2008; Raulin et al. 2012), is a rich laboratory for chemistry and processes that may resemble early Earth but with different materials in play (Coustenis and Taylor 2008). Furthermore, the presence of an internal liquid water ocean is more substantiated with new

measurements. And with its towering south polar plume of icy particles and water vapor, Enceladus is a geologically active moon, certainly a strong candidate for liquid water underneath its surface and energy sources, and incredibly important for the study of potentially habitable environments. Both of these moons are compelling targets for future exploration in that context, but in the meantime, Cassini-Huygens is providing us with major insights bearing high relevance to Astrobiology, the ► [origin of life](#), and habitability.

Titan

The Cassini orbiter and the Huygens descent probe were designed to be part of a common strategy to uncover the mysteries shrouding the enigmatic satellite of Saturn, ► [Titan](#). Titan is an organic paradise that is certain to tell us much about the chemical evolution that may lead to life. Water ice and ► [carbon dioxide](#) ice have been reported to exist currently on the surface. Transient episodes of melting of the water ice by either geologic activity or impacts would expose organics to aqueous alteration, as well as contact with carbon dioxide, leading potentially to reaction pathways that mimic those that occurred on the prebiotic Earth. No other place in the solar system has this type of ongoing chemistry. The Cassini-Huygens era of investigation has furthered our understanding of Titan as the largest ► [abiotic](#) organic factory in the Solar System.

Cassini-Huygens Space Mission, Fig. 6 Artwork showing the Cassini orbiter observing the Huygens probe landing site with VIMS and UVIS in 2008

Some essential breakthroughs related to Astrobiology within the realm of Saturn are summarized hereafter and on Fig. 7.

Titan's Atmosphere

With the current picture of Titan's organic chemistry, the chemical evolution of the main atmospheric constituents – ► [dinitrogen](#) (N_2) and methane – produces complex refractory organics through ► [photolysis](#) and ► [photochemistry](#). Measurements throughout the Titan atmosphere, both remotely and in situ, have indicated the presence of numerous hydrocarbon and ► [nitrile](#) gases, as well as a complex layering of organic ► [aerosols](#) that persists all the way down to the surface of the moon. The organic chemistry detected in the higher atmosphere by the Ion and Neutral Mass Spectrometer (INMS; Waite et al. 2007) provided feedback and useful information for all studies and models of the satellite's

chemical composition, complemented by measurements in the ► [stratosphere](#) made by the Composite Infrared Spectrometer (CIRS; Coustenis et al. 2010) and by the chemistry inferences from the Gas Chromatograph-Mass Spectrometer (GC-MS; Niemann et al. 2005), as well as density and temperature data retrieved by the Huygens Atmospheric Structure Instrument (HASI; Fulchignoni et al. 2005) during the descent to the surface near Titan's equator. The highly complex organic species in the ionosphere found by INMS are the precursors of the hydrocarbons and nitriles found in the stratosphere, which form aggregates and eventually condense out on the surface. Some of these chemical components are molecules of prebiotic interest (like hydrogen cyanide and HCN, Raulin et al. 2008). Thus, it appears that Titan is a chemical factory in which the formation of complex positive and negative ions is initiated in the high thermosphere as a

Cassini-Huygens Space Mission, Fig. 7 Some of the major discoveries that the Cassini-Huygens mission made on Titan: transient atmospheric phenomena (clouds) and several geomorphological features (dunes, cryovolcanoes, channels, mountains, and lakes) are shown in this composite. (Credit: G. Tobie)

consequence of magnetospheric-ionospheric-atmospheric interactions involving solar EUV, UV radiation, and energetic ions and electrons. Furthermore, seasonal variations of the atmospheric temperature and chemical composition have been recorded by the Cassini instruments.

The products accumulate on the surface, together with condensed volatile organic compounds such as HCN and benzene. The abundance of methane and its organic products in the atmosphere, seas, and dunes exceeds by more than an order of magnitude the carbon inventory in the Earth's ocean, biosphere, and fossil fuel reservoirs. Indeed, the measured value of the irreversible conversion of the methane in the atmosphere into higher-order organic/nitrile compounds that eventually end up deposited on the surface of Titan is near that of our terrestrial reference, indicating that methane is resupplied and converted at a rate that prevents the buildup of the heavier isotopologue over time as is the case of ► [nitrogen](#). However, the source of the atmospheric methane remains a mystery today although various models and hypotheses have been advanced, including its periodic outgassing from the interior via cryovolcanism.

The Cassini cameras and spectrometers, as well as the Huygens instruments, showed the presence of clouds and storms in Titan's atmosphere and described the distribution of the aerosols (haze) throughout the atmosphere. Most of the clouds detected in the past years were in Titan's southern hemisphere, as expected given the season on Titan that has been essentially probed (summer in the south), which means that solar heating is concentrated there. In recent years, however, they have been found to be building up also in the north as the season changes. Furthermore, temporal and even seasonal variations in the thermal structure and the chemical composition of Titan have been recorded by the Cassini instruments. During the Cassini mission, Titan's season moved from northern winter to northern spring, returning to the same configuration as during the Voyager encounter sometime in 2010. The same enhancement in the northern polar composition was found for most gases, but since mid-2012, a reversal has been monitored as the south pole is

now coming into winter exhibiting stronger signatures of gases and haze. The seasonal variations of the haze, whose vertical structure has changed with the detached layer dropping in altitude significantly in recent years, can be attributed to a varying Hadley circulation. Another important discovery was that the stratospheric zonal winds and temperatures in both hemispheres of Titan are symmetric about a pole that is offset from the surface pole by $\sim 4^\circ$.

Cassini-Huygens has also provided important information on the origin and evolution of Titan's atmosphere by measuring the noble gas concentrations (like argon for the first time) and their isotopic abundances, as well as the nitrogen and carbon stable isotopic ratios. These measurements also provide important clues about the overall role of escape, chemical conversion, outgassing, and recycling in the evolution of Titan's atmosphere.

Titan's Surface

Only with Cassini-Huygens did it become possible to acquire a clear picture of Titan's complex and exciting terrain. One of the most efficient applications of the synergy between the orbiter and the probe is the mapping of Titan's surface. While the Cassini orbiter provided detailed views of Titan's surface with its camera, mapping spectrometer, and radar, the Huygens probe, descending through the atmosphere on January 14, 2005, returned extraordinarily detailed images with resolutions ranging from 10 m at 10 km down to centimeters at the surface (Fig. 7). The Huygens Atmospheric Structure Instrument (HASI) gave the conditions of pressure, density, and temperature throughout Titan's atmosphere and in particular on Titan's surface to be 1.5 bar and 93.7 K (Fulchignoni et al. 2005), serving as a reference for many studies.

For the surface discoveries, the context is provided by the Cassini radar (RADAR), the Visual and Infrared Mapping Spectrometer (VIMS), and the Imaging Science Subsystem (ISS) data (Porco et al. 2005), while the ground truth was obtained by several of the Huygens instruments at the probe's ► [landing site](#), like the images and spectra of Descent Imager/Spectral Radiometer (DISR; Tomasko et al. 2005) or the composition

measurements of the GC-Ms (Niemann et al. 2005). Radar observations suggest that the ultimate fate of this aerosol precipitation is the generation of expansive organic-laden dunes (Lorenz et al. 2006; Radebaugh et al. 2008) that were observed around Titan's equator for the first time by Cassini (Fig. 7). These dunes are remarkable in being exactly the same size and shape as linear (longitudinal) dunes on Earth such as those found in the Namibian and Saharan desert and are essentially found near Titan's equator. Indeed, the mid latitude regions around the equator on Titan were found to be rather uniformly dark with some extensive bright regions (mostly elevated structures like mountains and ridges), while the poles are relatively bright but also filled with large dark areas now recognized as hydrocarbon "lakes" (mostly in the north pole) formed possibly by precipitation through the atmosphere. Few craters were detected on Titan's surface, which then appears rather young.

Radar-bright channels (probably cobbled streambeds like that at the Huygens landing site) have been observed at low and mid-latitudes, while channels incised to depths of several hundred meters are seen elsewhere, and at high latitudes, radar-dark, meandering channels are seen that suggest a lower-energy environment where deposition of fine-grained sediment occurs (Soderblom et al. 2007a; Lorenz et al. 2008a). Fluvial modification of the surface was very evident at the Huygens landing site (Tomasko et al. 2005). Radar and near-infrared imagery has revealed channels on much larger scales than those seen by Huygens.

Furthermore, in July 2006, Cassini found the first proof of hydrocarbon lakes near Titan's north pole (Stofan et al. 2007), which was confirmed in January 2007 (Mitri et al. 2007; Hayes et al. 2008). In March 2007, additional images near Titan's north pole discovered hydrocarbon "seas." These very dark features at the high northern latitudes of Titan were finally shown to be liquid-filled (most probably with ethane-rich mixtures; Brown et al. 2008; Raulin 2008, 2012; Cordier et al. 2012) basins – "lakes." The features range in size from less than 10 km² to at least 100,000 km². They are confined to the region

poleward of 55°N. To date, some 655 such features have been identified and mapped (Fig. 7). Other small lakes exist more to the south, like the Ontario Lacus. In 2010, specular reflections of the Sun off of Titan's northern lakes ("sunglints") were reported, while Cassini looked back toward a crescent Titan at high phase angle. The data were used to set some constraints on possible surface waves on a north polar lake (Jingpo Lacus), and since then observed specular reflections have been quite useful in corroborating the presence of large extents of liquid hydrocarbons in Titan's surface. The major seas on Titan, which are very extended in size, are namely Kraken Mare (surface area of at least 400,000 km² centered at 68 N, 310 W), Ligeia Mare (79 N, 248 W), and Punga (85 N, 339 W). Although some of these "seas" or "lakes" or even "oases" are found at mid latitudes, most are located in the northern hemisphere at Titan's current season, but they are expected according to some models to build up in the south, following the atmospheric evolution, as the season changes. In 2013, a study even reported the possible presence of blocks of hydrocarbon ice floating on the surface of these lakes.

Thus, the diversity of the terrains on Titan depicted by the Cassini-Huygens instruments includes a host of geologic features (Fig. 7):

- Erosional features such as channels and dendritic networks, possible lakes and seas, fluvial erosional deltas and other erosional and depositional constructs such as dunes (Radebaugh et al. 2008), possible glacial-flow constructs, etc.
- Impacts: the very low crater frequency is indicative of active geological surface processes
- Volcanotectonic features: domes, possible cryovolcanic flows, and bright spots (Sotin et al. 2005; Nelson et al. 2007; Lopes et al. 2013) as well as mountain chains (Radebaugh et al. 2007), many of these features may be active regions on Titan's surface

The features Cassini-Huygens discovered on Titan's surface were more complex than any expected, with landforms that seem to resemble the landscapes on Earth, including hills, dunes, a

deflated lakebed, but all composed of completely different constituents, many of which could be ices and organic material. The ambient conditions and direct measurement of methane evaporating from under the landed probe imply that the working erosive agent is liquid methane, not liquid water.

The surface of Titan, as revealed by the Cassini orbiter and the Huygens probe, offers us an opportunity to stretch our current models in an effort to explain the presence of dunes, rivers, lakes, cryovolcanoes, and mountains in a world where the rocks are composed of water ice rather than silicates and the liquid is methane or ethane rather than liquid water.

Titan's tectonism involves a number of very-large-scale linear features seen optically, notably the dark dune-filled basins. Some linear mountain ranges have been detected, several forming a chevron pattern near the equator, with a large bright terrain (Xanadu) extending over 3400 km in diameter. RADAR/SAR (synthetic-aperture radar (*SAR*)) imagery shows Xanadu to be extremely rugged.

As said before, the N_2 - CH_4 by-products in Titan's atmosphere eventually end up as sediments on the surface, where they accumulate presently at a rate of roughly 0.5 km in 4.5 Gyr. Since no large source was detected by Cassini to

resupply methane, cryovolcanic outgassing has been hypothesized, yet over what timescales and through which internal processes is unknown. Cassini-Huygens also found that the balance of geologic processes – impacts, tectonics, fluvial, aeolian – is somewhat similar to the Earth's, more so than for Venus or Mars. Titan may well be the best analogue to an active terrestrial planet in the sense of our home planet, albeit with different working materials (Solomonidou et al. 2013; Mueller-Wodarg et al. 2014).

In addition, the detection of Argon 40, and observations of what appear to be flows from cryovolcanoes, suggests that the interior of Titan is geologically active; theoretical calculations suggest a heat flow at present of about 8% that of the Earth, sufficient to mobilize water as liquid in the interior as the working fluid for ► [cryovolcanism](#). Cryovolcanism is a process of particular interest at Titan because of the known astrobiological potential of liquid water erupting onto photochemically produced organic molecules. Several likely cryovolcanic structures have been identified in Cassini near-infrared and radar images (Fig. 8). Although definitive evidence for active volcanism has not yet been produced, there are apparent surface changes in Cassini data that require explanation.

Cassini-Huygens Space Mission, Fig. 8

Cassini's major breakthroughs in our understanding of the Enceladus environment are connected to the southern polar region, where the magnetometer and the cameras detected plumes of gas and ice particles emanating from a series of warm fractures, dubbed the "tiger stripes"

Titan's overall density (1.88 g/cm^3) requires it to have roughly equal proportions of rock and ice. After its accretion, Titan was probably warm enough to allow differentiation into a rocky core with a water/ice envelope, but whether an iron or iron-sulfur core formed during the subsequent evolution remains uncertain. In addition, the presence of an internal liquid water ocean for Titan is supported by models, radar and gravity Cassini measurements, and the HASI experiment. The extremely low-frequency electric signal recorded by HASI was interpreted as a Schumann resonance between the ionosphere and a modestly conducting ocean roughly 50 km below the surface. Thermal evolution models suggest that Titan may have an icy crust between 50 and 150 km thick, lying atop a liquid-water ocean a couple of hundred kilometers deep, with some amount (a few to 30%, most likely $\sim 10\%$) of ammonia dissolved in it, acting as an antifreeze. Beneath lies a layer of high-pressure ice. Cassini's measurement of a small but significant non-synchronous contribution to Titan's rotation is most straightforwardly interpreted as a result of decoupling of the crust from the deeper interior by a liquid layer (Lorenz et al. 2008b). The presence of ammonia, from which Titan's nitrogen atmosphere was presumably derived, distinguishes Titan's thermal evolution from that of Ganymede and Callisto. The recent detection of periodic tidal stresses on Titan requires that its interior be deformable over timescales of the orbital period in a way that is consistent with a global ocean at depth (Iess et al. 2012). All of these indications make Titan a very likely habitable environment.

Enceladus

When Cassini had its first encounter with [▶ Enceladus](#) on February 17, 2005, the magnetometer instrument saw a bending of Saturn's magnetic field, with the plasma being slowed and deflected as it passed Enceladus. Data collected during the March 9, 2005, flyby provided further evidence of the existence of an atmosphere around the southern pole of Enceladus. The cosmic dust analyzer recorded thousands of hits from tiny particles of dust or ice coming from a cloud around the moon and feeding the adjacent E ring.

The Cassini spacecraft provided definitive proof that Enceladus is currently geologically active when multiple Cassini instruments detected plumes of gas and ice particles emanating from a series of warm fractures centered on the south pole, dubbed the "tiger stripes" (Fig. 8).

Cassini data strongly suggested the presence of liquid-water reservoirs that erupt in geysers on Saturn's moon Enceladus. Images had also shown particles of water in its liquid state emitted by icy jets and towering plumes. Several flybys of Enceladus followed bringing more data and revealing an extremely intriguing world (Fig. 9).

In March 2008, Cassini swept by Enceladus' south pole at an altitude of 52 km and plunged into a south polar plume, scooping up particles and gases to sample their composition. The gases that were "tasted" by Cassini's INMS bore a strong resemblance to the gases that issued from comets. All of the "fields and particles" Cassini instruments (the ones that measure the abundance, compositions, and motions of plasma, ions, atoms, molecules, particles, and magnetic fields in situ, wherever Cassini travels) have been sampling the plumes (Fig. 9).

Enceladus is thus the second cryovolcanically active icy satellite that has been identified (Triton is the only other known active icy satellite, but the process driving its cryovolcanism may not be linked to an internal heat source) and can be used to study active processes that are thought to have once played an important role in shaping the surfaces of other icy satellites. These processes include tidal heating, cryovolcanism, and ice tectonism, which all can be studied as they currently happen on Enceladus. Moreover, the plume source region on Enceladus samples a warm, chemically rich, environment that may facilitate complex organic chemistry and biological processes. CIRS on Cassini has demonstrated that the Enceladus south pole was the warmest portion of this moon, considerably much warmer than the equator (Spencer 2013).

Enceladus is arguably a place in the solar system where exploration is most likely to find a demonstrably habitable environment, and several researches point to the possibility that Enceladus' plumes, tectonic processes, and possibly a liquid-

Cassini-Huygens Space Mission, Fig. 9 One of the Cassini flybys of Enceladus when the spacecraft flew at quite low altitudes into the satellite's plumes (artistic impression)

water reservoir beneath the surface may create a complete and sustainable geochemical cycle that may allow it to support life. While other moons in the solar system have liquid-water oceans covered by kilometers of icy crust, in the case of Enceladus, the pockets of liquid water may be no more than tens of meters below the surface. Cassini has thus discovered a new potential ► [habitat](#) in our Solar System, well outside the traditional ► [habitable zone](#), which needs to be extended to include these “deep habitats.”

Future Directions

The primary mission for *Cassini* ended on July 30, 2008. However, given the excellent condition of the orbiter, the mission was extended to 2010. On February 3, 2010, NASA announced another extension for Cassini, this one for 6-1/2 years until 2017. The extension enables another 155 revolutions around the planet, 54 flybys of Titan, and 11 flybys of Enceladus.

However, even after these extensions, several questions and scientific themes remain that cannot be addressed by Cassini in its current configuration or with its present instrumentation. The two major themes in Titan exploration – the methane cycle as an analogue to the terrestrial hydrological cycle (Atreya et al. 2006) and the chemical

transformations of ► [complex organic molecules](#) in the atmosphere and the surface – render Titan a very high priority if we are to understand how volatile-rich worlds evolve and how organic chemistry and planetary evolution interact on large spatial and temporal scales. Both are of keen interest to planetology and astrobiology.

To answer the several remaining vital questions that Cassini has raised for Titan and for Enceladus, a new mission (the Titan Saturn System Mission, TSSM) was proposed and studied in 2008 by both ESA and NASA. This ambitious mission could bring the required long-term exploring capabilities combining an orbiter and two in situ elements (a montgolfière balloon and a lander) with state-of-the-art technology and instruments (see www.lesia.cosmicvision/tssm/tssm-public). After this study, other, simpler but also exciting, mission concepts have also been proposed for a return to the Saturnian system within the next two or three decades to study Titan with orbiters, lake landers, balloons, airplanes, etc.

Catabolism

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Definition

Catabolism is the subset of metabolic networks by which organic compounds are degraded to simpler organic or inorganic compounds. Catabolism includes oxidation reactions – coupled to the reduction of coenzymes such as NAD⁺ or FAD – and sometimes substrate-level phosphorylation steps leading to ATP synthesis.

Catalyst

Henderson James Cleaves

Earth-Life Science Institute (ELSI), Tokyo

Institute of Technology, Tokyo, Japan

Blue Marble Space Institute of Science, Washington, DC, USA

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Definition

In chemistry, catalysts are compounds that increase the rate of a reaction but are not consumed in the reaction, as a reagent would be. They can therefore generally participate in reactions multiple times. The term “catalyst” is derived from the Greek word *καταλύειν*, meaning to dissolve or loosen. Catalysts may be metals, mineral surfaces, ► [enzymes](#), ► [ribozymes](#), or small organic molecules, among other possibilities.

Catalysts operate by changing the rate-limiting free energy change to the transition state relative to that of the corresponding uncatalyzed reaction, resulting in a larger reaction rate at a given temperature. The physical mechanism of catalysis can be complex. Catalysts may affect the reaction environment or bind to the reagents to polarize bonds forming intermediates that do not occur in the cognate uncatalyzed reactions. Catalysts have no effect on the chemical equilibrium of a reaction because the rates of both the forward and reverse reactions are affected.

In catalyzed reactions, as in uncatalyzed reactions, the overall reaction rate depends on the frequency of collision of the reactants in the rate-limiting step. The catalyst usually acts in this limiting step, and rate changes are proportional to the amount of catalyst present. As catalysts are not consumed in a reaction, only small amounts may be needed to increase the rate of the reaction significantly. In reality, however, catalysts are sometimes inhibited, deactivated, or destroyed

via secondary processes. Substances that reduce the activity of catalysts are called inhibitors if the reduction is reversible and poisons if the reduction is irreversible.

Catalysts can be heterogeneous or homogeneous, depending on whether they exist in the same phase as the substrate. Heterogeneous catalysts act in a different phase than the reactants, for example, solids that act on liquid or gaseous substrates. Homogeneous catalysts function in the same phase as the reactants, for example, cytosolic enzymes are examples of homogeneous catalysts.

Catena, Catenae

Roland J. Wagner
German Aerospace Center (DLR), Institute of
Planetary Research, Berlin, Germany

Synonyms

[Crater chain](#)

Definition

A catena is a linear, slightly curved, or sinuous chain of circular to elliptical depressions. The depressions can be surrounded by raised rims and are contiguous or separate. A crater chain may originate from volcanic or impact processes. Depressions in volcanic catenae are generally rimless. Raised rims and a more-or-less uniform size distribution of the depressions are characteristic of impact crater chains. Impact catenae are created

(a) either by fragments of a projectile that disintegrated prior to impact or (b) by material ejected when a crater is formed, forming chains of secondary craters.

Synonyms

Charge-coupled device

Definition

CCD is the abbreviation for charge-coupled device. A CCD is a photoelectronic imaging

CCD, Fig. 1 The principle of charge transfer from one pixel to the next one in a CCD. *Top:* photons penetrate the substrate and create electrons. *Middle:* the electrons are attracted and stored below an electrode polarized with a positive voltage and isolated from the substrate, thanks to a thin layer of silicon oxide. *Bottom:* a voltage is applied to the next electrode and reset on the first one so that electrons travel one step. The procedure is repeated until all pixels are read at the end of the chain

device commonly used for astronomical observations in the visible domain. A CCD is a solid-state silicon-based detector where each of the numerous pixels (up to ten million) stores in a potential well the electrons produced by photons (one to one). At the end of the exposure, charges are transferred from one pixel to the next, up to the output amplifier, by manipulation of voltages applied to surface electrodes (see Fig. 1). Back-illuminated (or thinned) CCDs feature an excellent quantum efficiency for wavelengths up to $\lambda = 1 \mu\text{m}$. Because of their better efficiency and the convenience of obtaining directly a digital image at the output, CCDs definitely replaced photographic plates for use in astronomy in the 1980s, especially since it has been possible to tile side by side several CCDs (up to several tens) and produce cameras with a wide sensitive surface.

Definition

The cell is the smallest unit of living matter capable of performing all the activities necessary for life (Alberts et al. 1994). In fact it is the smallest structure with a complete metabolism because it has all the physical and chemical components needed for its own maintenance and growth. All living organisms are made of cells. The simplest forms of life are individual cells that propagate by division, while more complex organisms are multicellular, that is, their bodies are cooperatives of many kinds of specialized cells that could not survive for long time by themselves.

History

The first person to use the word “cell” was Robert Hook (1665) who described what he called the *cella* in a piece of cork (Fig. 1). He used this term because the cork appeared to be composed of thousands of small chambers that resembled the individual sleeping rooms in monasteries. However, Antonie Philips van Leeuwenhoek (1632–1723) using his handcrafted microscopes was the first to observe and describe single-celled microbial organisms, which he originally referred to as *animalcules*. After Van Leeuwenhoek, in 1838 a botanist, Matthias Jakob Schleiden, and a

zoologist, Theodor Schwann, formally proposed “The Cell Theory” stating that: (1) all organisms are composed of one or more cells, (2) all cells come from preexisting cells, (3) vital functions of an organism occur within cells, and (4) all cells contain the hereditary information necessary for regulating cell functions and for transmitting information to the next generation of cells. Their theory, which nowadays seems so obvious, was a milestone in the development of modern biology. The cell theory was extended in 1855 by Rudolf Virchow, who stated that new cells come into existence only by the division of previously existing cells. Cells cannot arise by spontaneous generation from nonliving matter (Campbell and Reece 2002).

Overview

At first sight, cells exhibit a staggering diversity. Some lead a solitary existence, others live in communities; some have defined geometric shapes, others have flexible boundaries; some swim, some are sedentary. However, all cells have several basic features in common: they are bounded by a plasma membrane that physically separates them from the outside environment. Within the membrane is a semifluid substance, cytosol, composed mostly of water (70–90 %). In the cytosol is where a variety of specialized structures named ► [organelles](#) are located. All cells contain also chromosomes, carrying genes for synthesizing all the proteins needed for cell growth, repair, and reproduction.

Despite all the different cell morphologies, it is surprising that there are only two types of cells. Based on differences in compartmentalization, cells can be divided into prokaryotic cell, the simplest, and the more complex eukaryotic cell (Fig. 2). By definition, prokaryotes are those organisms whose cells are not subdivided by membranes into a separate nucleus and cytoplasm. All prokaryote cell components are located together in the same compartment; the genetic material (DNA) is concentrated in a region called the nucleoid, but no membrane separates this region from the rest of the cell. On the contrary, eukaryotic cells contain a membrane-bound

Cell, Fig. 1 Portraits of Robert Hook and Antonie Philips van Leeuwenhoek, two of the founders of cell biology and microbiology. Below them, the portraits of Matthias Jakob Schleiden and Lynn Margulis, known for their cell theory and endosymbiotic theory respectively

organelle named nucleus where the genetic material is contained. Only bacteria and archaea are prokaryotic cells. Protists, plants, fungi, and animals are eukaryotic cells (Bolsover et al. 1997).

Prokaryotic cells are simpler and generally smaller than eukaryotic cells and are thought to have evolved first (Fig. 3). Fossils show that prokaryotic organisms antedate by at least 2 billion years the first eukaryotes, which appeared some 1.5 billion years ago. It is likely that eukaryotes evolved from prokaryotes. The most plausible explanation of this process is known as the endosymbiotic theory, first articulated by the Russian botanist Konstantin Mereshkowsky in 1905. The endosymbiotic theory was advanced and substantiated with microbiological evidence by Lynn Margulis in a 1967 paper, *The Origin of Mitosing*

Eukaryotic Cells. The basis of this theory concerns the origins of mitochondria and plastids (e.g., chloroplasts), which are organelles of eukaryotic cells. According to this theory, these organelles originated as separate prokaryotic organisms that were taken inside the cell as endosymbionts. Mitochondria developed from proteobacteria (in particular, Rickettsiales or close relatives) and chloroplasts from cyanobacteria (Margulis 1967).

In addition, prokaryotic cells also lack most other membrane-bound organelles typical of eukaryotic cells. In some prokaryotic cells the plasma membrane is folded inward to form a complex of internal membranes (the mesosome) along which the relations of cellular respiration are thought to take place. Photosynthetic

Cell, Fig. 2 Although all the cells have several basic features in common, there is a great variety of specific cellular body plans. Some cells are organisms in their own right, and some make up the bodies of multicellular organisms. (a) Mixed diatoms, these algae are single-cell or colonial and are surrounded by a rigid siliceous envelope named theca. (b) Bacterial cells belonging to the species *Escherichia coli* a rod-shaped bacterium that is commonly found in the lower intestine of warm-blooded organisms. (c) Amoeba cell, this small protozoan uses tentacular protuberances called pseudopodia to move and phagocytose smaller unicellular organisms, which are enveloped inside the cell's cytoplasm in a food vacuole, where they are slowly broken down by enzymes. (d) *Euglena* cell, a photosynthetic protist with at least

150 described species. The cells are cylindrical with a rounded anterior and tapered posterior. The chloroplasts are well-developed and can glide and swim using their flagella. (e) White and red blood cells also referred to them as leucocytes and erythrocytes principal cells of the immune system involved in defending the body against both infectious disease and foreign materials and cells involved in delivering oxygen to the body tissues via the blood flow through the circulatory system. (f) *Spirogyra* cells, a filamentous green algae named for the helical or spiral arrangement of the chloroplasts. It is commonly found in freshwater areas, and there are more than 400 species of *Spirogyra* in the world. *Spirogyra* measures approximately 10–100 μm in width and may stretch centimeters long

prokaryotes contain chlorophyll associated with flat membranes called lamellae. On the contrary, eukaryotic cells have many types of membrane-bound organelles that partition the cytoplasm into compartments.

Typically, each prokaryotic cell has a single chromosome carrying a full set of genes providing

it with the genetic information necessary to operate as a living organism. Each chromosome has 3,000–4,000 genes although some have as few as 500. A typical prokaryotic cell is rod shaped and about 2–3 μm long and 1 μm wide (1 μm = 0.001 mm). However, bacteria are not limited to a rod shape; spherical, filamentous, or spirally twisted

Cell, Fig. 3 Schematic representation of the cell composition. (a) Prokaryotic cells, (b) eukaryotic animal cells. Despite their apparent differences, both cell types have a lot in common. They perform most of the same kinds of functions, and in the same ways. All are enclosed by plasma membranes, filled with cytoplasm, and loaded with small structures called ribosomes. They have DNA

which carries the archived instructions for operating the cell. Physiologically they are very similar in many ways. For example, the DNA in the two cell types is precisely the same kind of DNA, and the genetic code for a prokaryotic cell is exactly the same genetic code used in eukaryotic cells

bacteria are also found. Eukaryotic cells are generally much bigger than prokaryotes. Size is a general aspect of cell structure that relates to function. At the lower limit, the smallest cells

known are bacteria called Mycoplasmas, which have diameters between 0.1 and 1.0 μm . Eukaryotic cells are typically ten times bigger than bacteria.

There are two distinct types (Domains) of prokaryotes, the ► **Bacteria** and ► **Archaea**, which are no more genetically related to each other than either group is to the eukaryotes. Both show the typical prokaryotic structure where the nucleus and other internal membranes are lacking. Despite this visual similarity to bacteria, archaea possess genes and several metabolic pathways that are more closely related to those of eukaryotes: notably the proteins involved in transcription and translation. Other aspects of archaean biochemistry are unique, such as their reliance on ether lipids in their cell membranes and cell wall. The cell wall of bacteria is always made of peptidoglycan, a molecule unique to this group or organisms. Archaea often have cell walls, but peptidoglycan is never present. Thus, the only well defined cellular structures presented by prokaryotes, the cell membrane and cell wall, are chemically quite different in these two groups or organisms. Initially, archaea were seen as extremophiles that lived in harsh environments, such as hot springs and salt lakes, but they have since been found in a broad range of habitats, such as soils, oceans, and marshlands. Archaea are particularly numerous in the oceans, and the archaea in plankton may be one of the most abundant groups of organisms on the planet (Clark 2005).

In addition to the plasma membrane, a eukaryotic cell has extensive and elaborately arranged internal membranes, which partition the cells into compartments. The nucleus is surrounded by a double membrane, the nuclear membrane, which separates the nucleus from the cytoplasm, but allows some communication with the cytoplasm via nuclear pores. The nucleus contains most of the genes in the eukaryotic cell (although some genes are located in the mitochondria and chloroplasts). The genome of eukaryotes usually consists of 10,000–50,000 genes carried on several ► **chromosomes**. In a cell that is not dividing, DNA is organized along with proteins forming an irregular network of strands termed chromatin. When the cells began the process of nuclear division (mitosis), the chromatin coils and condenses into discrete chromosomes containing several thousand genes arranged in a specific linear

order. Most eukaryotes are diploid, with two copies of each chromosome. Consequently, they possess at least two copies of each gene.

Besides nucleus, eukaryotic cells contain a variety of ► **organelles**, which are subcellular structures that carry out specific tasks. Some of them are separated from the rest of the cytoplasm by membranes but others are not. Many of the different membranes of the eukaryotic cell are forming an extensive complex of branching tubules, named endoplasmic reticulum (ER) that is continuous with the nuclear envelope and permeates the cytoplasm. The ER manufactures membranes and performs many other biosynthetic functions such as synthesis of lipids, metabolism of carbohydrates, and detoxifications of drugs and toxins. The ER also functions as a system for transporting materials from one part of the cell to another and perhaps to the outside environment as well. The Golgi apparatus is a stack of flattened membrane sacs and associated vesicles that is involved in the secretion of the proteins manufactured along the ER. The proteins are released from the ER in sealed-off little vesicles that fuses with the membranes of the Golgi complex. Within the Golgi complex the proteins are modified in various ways (i.e., adding carbohydrates forming glycoproteins). The Golgi apparatus in plant cells produces polysaccharides used to construct the cell wall.

Other organelles related to cell metabolism are the lysosomes, membrane-bound structures specialized for digestion that contain hydrolytic enzymes that cells use to digest macromolecules. About 40 different enzymes have been identified in lysosomes. In addition, mitochondria and ► **chloroplasts** are the main energy transducers of cells. Mitochondria are generally rod-shaped organelles bounded by a double membrane. They resemble bacteria in their size and shape; it is thought that mitochondria are indeed evolved from bacteria that took up residence in the primeval ancestor of eukaryotic cells. Like bacteria, mitochondria contain a circular molecule of DNA similar to a bacterial chromosome, although much smaller. Mitochondria are the site of most of the chemical reactions that convert the chemical energy present in inorganic compounds to another

form of energy, ATP, that cells can use for work. These organelles are the sites for cellular respiration, the catabolic process that generates ATP by extracting energy from sugars, fats, and other compounds with the help of oxygen. This contrasts with bacteria, where the respiration chain is located in the cytoplasmic membrane, as no mitochondria are present (Davis et al. 1990).

► **Chloroplasts** are also membrane-bound organelles that produce and store food materials in algae and plant cells. Chloroplasts contain the light-absorbing pigment chlorophyll, along with enzymes and other molecules that function in the photosynthetic production of reduced carbon molecules by trapping light energy. Like mitochondria, chloroplasts contain a circular DNA molecule and are thought to have evolved from a photosynthetic bacteria. Chloroplasts also contain a variety of yellow and orange pigments known as carotenoids. Although a unicellular alga may have only a single large chloroplast, cells of complex plants may possess 20–100 of these organelles.

Besides for the presence of chloroplasts, plant cells differ from animal cells in several other ways. Although all cells are limited by plasma membranes, plant cells are also surrounded by ► **cell walls** of cellulose, which limits any change of position and shape. In addition, most plants have one large or several small compartments called vacuoles, used for storing nutrients and waste products, and certain organelles such as centrioles and lysosomes are absent.

There are still other structures that support the cells, connect them with other cells, and help them move. Cytoskeletal elements, such as microtubules or microfilaments, give cells their shape and allow the movement. Centrioles are tiny organelles that function in nuclear division, usually located within a dense area of cytoplasm, the centrosome. Cells are able to swim or move by using their cilia and flagella, which are specialized arrangements of microtubules (Maton et al. 1997).

Cell Origin and Evolution

Synthesis and accumulation of biologically relevant molecules in the early Earth would have been the first step in the path to the primitive cells. It is generally assumed that RNA was the first

information storage molecule and that DNA came later. The primitive cell vaguely resembled a bacterium (Bada and Lazcano 2010).

Life began remarkably early in Earth's history, and those first organisms were ancestral to the great diversity of life we observe today. The Earth was formed about 4.5 billion years ago. However, the oldest fossils of organisms known are 3.5 billion years old. These microfossils resemble certain bacteria that still exist today. For bacteria so complex to have evolved by 3.5 billion years ago, it is a reasonable hypothesis that life originated much earlier, when Earth began to cool to a temperature at which liquid water could exist. The fossil record supports the presumption that prokaryotes were the earliest organisms. Photosynthesis probably evolved very early also in prokaryotic history. The photosynthetic bacteria that generate and release oxygen to the atmosphere, named cyanobacteria, probably evolved over 2.7 billion years ago. The accumulation of atmospheric oxygen was gradual and had an enormous impact on life since oxygen attacks chemical bonds and was toxic for many of the existing prokaryotic groups. Although some prokaryotic species survived in habitats that remained anaerobic, a variety of different adaptations to the oxydizing atmosphere evolved, including cellular respiration, using oxygen to obtain energy from organic and inorganic molecules.

The oldest fossils of eukaryotes are 2.1–2.7 billion years old, and look like simple single-celled algae. This range of time places the earliest eukaryotes during a time when the oxygen evolution was changing Earth's environments dramatically. Development of chloroplasts may be part of the explanation for this temporal correlation.

It seems reasonable to suggest that eukaryotes evolved from a single prokaryotic ancestor that gradually accumulated greater structural complexity. But evidences show that the eukaryotic cell originated from a symbiotic coalition of multiple prokaryotic ancestors not just one. The theory of serial endosymbiosis proposes that mitochondria and chloroplasts were formerly small prokaryotes living within larger cells (Margulis 1967; Davis et al. 1990). The proposed ancestors of mitochondria were aerobic

Cell, Fig. 4 Microscopes and their images. (a) A confocal microscope creates sharp images of a specimen that would otherwise appear blurred when viewed with a conventional optical microscope. This is achieved by excluding most of

the light from the specimen that is not from the microscope's focal plane. (b) A glia neuron cell viewed using confocal microscopy. (c) Transmission electron microscope (TEM) uses a high energy electron beam transmitted

heterotrophic prokaryotes, related to alpha-proteobacteria, that became endosymbionts. The proposed ancestors of chloroplasts were photosynthetic prokaryotes related to cyanobacteria. These ancestors probably gained entry to the host cell as undigested prey or parasites. Evidences supporting this idea are the structural similarity between bacteria, mitochondria, and chloroplasts; both organelles are able to replicate by a splitting process reminiscent of binary fission in bacteria, and each organelle contains a genome consisting of a single circular DNA molecule not associated with histones or other proteins, as in most prokaryotes. Furthermore, the organelles contain all the enzymatic equipment necessary to transcribe and translate their DNA into proteins. During the evolution from endosymbiont to organelle, the vast majority of the original bacterial genes has been lost or transferred to the host nucleus; so the organellar genomes are very reduced in comparison to their closest free-living counterparts.

Basic Methodology

Living cells are composed of many progressively smaller components. Most levels of biological organization are imperceptible to the human senses, so that to study them we must make use of a variety of instruments and indirect techniques. Microscopy is the most useful technique to study cell structure and related issues. The light microscope, gradually improved since Hooke's time, uses visible light as the source of illumination. During the last decades, the development of the electron microscope has enabled researchers

to study the fine detail, called ultrastructure of cells. Nowadays, the scanning tunneling electron microscope allows us to study the relationship between molecules.

Magnification is the ratio of the size of the image to the size of the specimens. Whereas the ordinary light microscope can magnify a structure about 1,000 times, the electron microscope can magnify up to 250,000 times or even more. Besides, the electron microscope has far superior resolving power, which is the ability to reveal fine detail, and is expressed as the minimum distance between two points that can be distinguished as separate and distinct points.

Optical and electron microscopy involve the diffraction, reflection, or refraction of electromagnetic radiation/electron beams interacting with the subject of study, and the subsequent collection of this scattered radiation in order to build up an image. This process may be carried out by wide-field irradiation of the sample (e.g., standard light microscopy and transmission electron microscopy) or by scanning of a fine beam over the sample (e.g., confocal laser scanning microscopy and scanning electron microscopy) (Fig. 4).

Optical or light microscopy involves passing visible light transmitted through or reflected from the sample through a single or multiple lenses to allow a magnified view of the sample. The resulting image can be detected directly by the eye. To be viewed with the light microscope, specimens must be very thin. Single cell organisms can be observed *in vivo*. There are important limitations to the standard optical microscopy: the technique can only image dark or strongly refracting objects efficiently, diffraction limits resolution to approximately 0.2 μm ,

Cell, Fig. 4 (continued) through a very thin sample to image and analyze the microstructure of materials with atomic scale resolution. The electrons are focused with electromagnetic lenses and the image is observed on a fluorescent screen, or recorded on film or digital camera. **(d)** A TEM image of the green algae *Chlamydomonas*. We can observe the ultrastructure of the nuclei, chloroplasts, and pyrenoid. **(e)** Scanning electron microscope (SEM), while TEM allows us to study the inner structure of objects (tissues, cells, viruses) and SEM is used to visualize the

surface of tissues, macromolecular aggregates, and materials. **(f)** An SEM image of a diatom, brown algae. We can see the silica theca that surround the cells with their characteristic patterns specific for each species. **(g)** The scanning tunneling microscope (STM) provides a picture of the atomic arrangement of a surface by sensing corrugations in the electron density of the surface that arise from the positions of surface atoms. **(h)** An STM image of palladium crystals

and out of focus light from points outside the focal plane reduces image clarity. Live cells generally lack sufficient contrast to be studied successfully. Internal structures of the cell are colorless and transparent.

The electron microscope uses a beam of electrons as a source of illumination instead of light. The microscope has a greater resolving power than a light-powered optical microscope, because it uses electrons that have wavelengths about 100,000 times shorter than visible light (photons), and can achieve magnifications of up to 1,000,000 times. The electron microscope uses electrostatic and electromagnetic “lenses” to control the electron beam and focus it to form an image. Two types of electron microscopes in common use are the transmission electron microscope and the scanning electron microscope (Murphy 2002).

Definition

The ► [cell](#) membrane is the boundary that envelops all cells and provides a semipermeable barrier for their separation from the extracellular environment. It is constituted by a 5–8-nm-thick lipid bilayer – mainly composed of amphiphilic phospholipids – in which membrane proteins are interspersed. The cell membrane is involved in different cellular processes including active and passive traffic of substances, signal transduction, and cell adhesion and fusion. In addition to the cell membrane, inside the eukaryotic cytoplasm, there are membrane-enclosed ► [organelles](#). These specialized compartments include the nucleus, mitochondria, plastids, Golgi apparatus, vacuoles, vesicles, lysosomes, peroxisomes, and endoplasmic reticulum. Mitochondria, present in almost all eukaryotes, and plastids, present in photosynthetic eukaryotes, are double-membrane organelles, a feature indicative of their endosymbiotic origin. ► [Bacteria](#) and archaea lack membrane-enclosed compartments, with certain exceptions

such as the magnetosomes present within the nucleocytoplasm of magnetotactic bacteria and the cell compartments observed in bacteria from the phylum Planctomycetes. Some ► [virus](#) families – the so-called lipid coated viruses – are also surrounded by a membrane during their extracellular phase, derived from the host cell previously infected.

Definition

Cell models are laboratory versions of simple cellular structures that exhibit some of the properties of the living state. They consist of a compartment, usually microscopic lipid vesicles,

with encapsulated functional polymers such as enzymes and nucleic acids.

History

The idea that it might be possible to assemble model cells can be traced back to 1965, when Alec Bangham discovered that phospholipids spontaneously self-assemble into closed compartments (now called liposomes) when dispersed in aqueous phases (see review by Bangham 1993). The boundary of such compartments is a ► [lipid bilayer](#) that is relatively permeable to water and small molecules like water but much less permeable to ionic solutes such as sodium and potassium ions. Efraim Racker took the next step toward cell models when he and his coworkers showed that it was possible to use detergents such as deoxycholic acid to disperse membranous components of cells (see Racker 1970). When the detergent was removed, small vesicles formed that contained the original lipids and functional proteins. Using this method, Racker and his colleagues were able to reconstitute electron transport reactions of mitochondrial and chloroplast membranes.

Similar techniques were soon applied to other biological structures and functions. For instance, Oesterhelt and Stoekenius (1971) reconstituted the proton pump of purple membranes isolated from a species of *Halobacterium* (now recognized as archaeon, rather than a bacterium) that uses the energy of a proton gradient to synthesize ATP. Racker and Stoekenius then collaborated to produce a system of reconstituted membrane vesicles containing both the proton pump of *Halobacterium halobium* and the ATP synthase of mitochondria (Racker and Stoekenius 1974). The hybrid structures could synthesize ATP using light as an energy source, which strongly confirmed Peter Mitchell's chemiosmotic hypothesis that proton gradients could drive ATP synthesis (Mitchell 1976).

When it was realized that lipid vesicles could incorporate enzymatic functions, the next step toward model cells became feasible, in which a polymerase encapsulated in liposomes would be

able to synthesize a nucleic acid. This was first attempted by Chakrabarti et al. (1994) and Walde et al. (1994) both reporting that encapsulated polynucleotide phosphorylase could synthesize an RNA homopolymer from its substrate, in this case ADP.

Overview

The point of this brief history is that relatively complex biological functions can be reconstituted by ► [self-assembly](#) of their dispersed components, so it is reasonable to consider the possibility that similar techniques might allow artificial cells to be fabricated under laboratory conditions. If this turns out to be possible, perhaps it will help define “life” and even elucidate the major steps that led to the origin of cellular life nearly four billion years ago.

Basic Methodology

What would such a system do? This question can be answered by listing the properties and functions of model cells that could conceivably be assembled in the laboratory. For the purposes of this list, it is assumed that all the nutrients and energy needed for growth and replication will be provided so that a complex metabolism will not be required:

1. Self-assembly of lipid molecules generates cellular compartments defined by boundary membranes.
2. Macromolecules are encapsulated in the compartments, yet smaller substrate molecules can cross the membrane barrier.
3. The macromolecules have the potential to grow by polymerizing the substrate molecules.
4. The membrane itself can grow by addition of lipid molecules.
5. Some of the encapsulated polymers are catalysts that can speed the growth process, and the catalysts are reproduced during growth by polymerization.
6. Genetic information is contained in the sequence of monomers in a second set of polymers and is used to direct the growth of catalytic polymers.
7. The catalytic polymers catalyze the polymerization of the genetic molecules.
8. Following a certain amount of growth, the membrane-bounded system of macromolecules divides into smaller structures, each containing the catalysts and copies of genetic information.
9. Genetic information is passed between generations by duplicating the gene sequences and sharing them between daughter cells.
10. Occasional mistakes (mutations) occur during replication or transmission of genetic information so that the system can evolve through selection.

Key Research Findings

Several research groups are beginning to study systems of genetic and catalytic molecules that are steps toward fulfilling this list of properties. For instance, Mansy et al. (2008) demonstrated that it was possible to encapsulate a short DNA template in fatty acid vesicles, then add activated nucleotides outside. The nucleotides were sufficiently permeable to enter the vesicle interior and support the sequence-dependent elongation of the DNA. In a related advance, Lincoln and Joyce (2009) developed a pair of ribozymes, each of which could catalyze the synthesis of the other by a ligation reaction that joined two smaller non-catalytic oligonucleotides. This system is not encapsulated and does not replicate a complete base sequence but illustrates in principle how an evolving system of paired ribozymes could function. The Rasmussen Group in Denmark has stepped away from biologically inspired molecular systems and is attempting to assemble a very different version of model cells (DeClue et al. 2009). In their system, the reactions occur on the surface of vesicles, rather than the interior, thereby bypassing the requirement for membrane transport of the nutrients. Furthermore, they are attempting to drive the polymerization reaction

by an input of light energy, rather than supplying activated monomers.

Another approach to model cells is to encapsulate ribosomes and translation systems in lipid vesicles. Luigi Luisi and his coworkers at the Eidgenössische Technische Hochschule in Zurich, Switzerland, made the first attempt to assemble a translation system in lipid vesicles by encapsulating ribosomes and an RNA homopolymer that codes for phenylalanine (Oberholzer et al. 1995). The phenylalanine was attached to transfer RNA so that it was ready to be used by ribosomes for peptide synthesis. However, the lipid bilayer was impermeable to the transfer RNA, so peptide bond formation was limited to the small number of tRNA-amino acid complexes that were encapsulated within the vesicles. This limitation makes the point that model cells need to have some way to transport nutrients inward across their boundary membrane.

Noireaux and Libchaber (2004) reported an elegant solution to the permeability problem. They disrupted *E. coli* cells and captured samples of the bacterial cytoplasm in lipid vesicles. The samples included ribosomes, transfer RNAs, and the hundred or so other components required for protein synthesis. The researchers then chose two genes to translate, one for green fluorescent protein (GFP), a marker for protein synthesis, and a second gene for a pore-forming protein called alpha hemolysin. If the system had worked as planned, the GFP would have accumulated in the vesicles as a visual marker for protein synthesis and the hemolysin would have allowed externally added “nutrients” in the form of amino acids and ATP to cross the membrane barrier and supply the translation process with energy and monomers. The system was functional, and the newly synthesized hemolysin allowed synthesis of GFP to continue for as long as four days. The GFP in the vesicles was monitored by its green fluorescence. A more recent example of a model cell system is the encapsulated “genetic cascade” fabricated by Ichihashi et al. (2010), in which a gene on a plasmid was transcribed by RNA polymerase to mRNA, which in turn directed the synthesis of green fluorescent protein.

The model cells containing ribosomes clearly demonstrate one fundamental property of life: they can use genetic information to synthesize a protein. Although they can grow by synthesizing one or more specific proteins, no other cellular components are produced. To approach the definition of a living system, the vesicles would need to incorporate genetic information required for a hundred or more different proteins and RNA species, over half of which are the components of the ribosomes themselves. They would need genes for polymerase enzymes so that the DNA could be replicated as part of the growth process, and a way for lipid to be synthesized, because the membranous boundary must grow to accommodate the internal growth. Transport proteins must be synthesized and incorporated into the lipid bilayer; otherwise, the vesicles have no access to external sources of nutrients and energy. A whole set of regulatory processes must be in place so that all of these functions are coordinated. Finally, when the vesicles grow to approximately twice their original size, there must be a way for them to divide into daughter cells that share the original genetic information.

It seems impossible that the first forms of life sprang into existence with such a complex system of interacting molecules. There must have been something simpler, a kind of scaffold life that was left behind in the evolutionary process leading to today’s life. Can we reproduce that scaffold? This is the challenge for research on model cells and the origin of life.

Applications

A functioning system of artificial cells will represent a major breakthrough in biotechnology. At present, the pharmaceutical industry must use recombinant DNA techniques and bacterial cultures to synthesize protein products. Model cells are simplified versions of bacterial cells, and if they can be designed to produce a desired protein in large quantities, the result would be a much more efficient, flexible, and inexpensive system for producing important therapeutic agents. See review by Pohorille and Deamer (2002).

Future Directions

One promising approach to model cells is suggested by the results reported by Lincoln and Joyce (2009). It is possible that a pair of ribozymes will be found that can catalyze their own complete synthesis using genetic information encoded in their base sequences. If the ribozymes could then function in a membrane-bounded compartment using nucleotides present in the external medium, the system could rightly be claimed to have the essential properties that are lacking so far in artificial cell models: reproduction of the catalysts and genetic information in a cellular compartment.

Cell Wall

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

The cell wall is an external layer that surrounds some types of ► [cells](#). It has structural, protective, and functional roles (filtering capacities for the selective uptake of substances for cell metabolism). It is located outside the cell membrane. The cell wall is found in bacteria, plants, fungi, algae, and some Archaea. The main functions of cell walls are (1) to provide tensile strength and limited plasticity to the cell, (2) to provide mechanical support, (3) cutinized, it is used to prevent water loss, (4) to provide mechanical protection, and (5) to contribute to cell-cell communication. The structure of the cell wall differentiates Gram-positive from ► [Gram-negative bacteria](#), a property of important phylogenetic value.

Keywords

Minimal genome · Synthetic biology · Top-down approach · Bottom-up approach

Definition

A minimal cell is a hypothetical biological system that possesses only the necessary and sufficient attributes to be considered alive. Therefore, it must be able to maintain its own structures (homeostasis), self-reproduce, and evolve in a supportive, protected, and stable environment.

Overview

A minimal living cell must still retain all essential genes needed to perform all essential functions, that is, a minimal genome. However, there is no conceptual or experimental support for the existence of *one* form of minimal cell. Different essential functions can be defined depending on the environment, and numerous versions of minimal genomes can be envisaged to perform such functions even in the same conditions (Koonin [2003](#)). Computational and experimental studies (mostly bacterium centered) to define the characteristics of a minimal cell (reviewed in Feher et al. [2007](#); Moya et al. [2009](#)), converge in the conclusion that different minimal hypothetically viable cells can be conceived, possessing a universal genetic machinery supported by a diversity of minimal ecologically dependent metabolic charts (Gil et al. [2004](#)).

Defining the minimal genome does not fully define a minimal cell. Several levels of complexity (topological genome architecture, transcriptome, proteome, metabolome, and interactome) that are not taken into account in minimal genome studies (Fisunov et al. [2011](#)) can be explored through theoretical computer models based on the massive amount of molecular and cellular biology data available (Di Ventura et al. [2006](#); Shuler et al. [2012](#); Goldberg et al. [2018](#); Martínez and Reyes-Valdés [2018](#)). However, to date, no single computational method can fully explain complex phenotypes in terms of molecular components and their interactions, and it is difficult to determine and model all parameters involved (Karr et al. [2012](#)).

Nowadays, one of the main goals of synthetic biology is the generation of minimal cells, to improve our basic understanding of living

systems and to be used as containers for introducing genetic modules to customize cells for biotechnological purposes (Moya et al. 2009). There are two complementary and alternative ways to do so, namely *top-down* and *bottom-up* approaches. The *top-down* strategies, also called genome-driving cell engineering (O'Malley et al. 2008), start from simple modern cells and intend to simplify them further through the removal of non-essential genetic elements. The *bottom-up* approaches aim at constructing the simplest system that could be considered alive from scratch (Luisi 2002), by putting together the essential non-living components: a self-replicating nucleic acid, a metabolic machinery, and an encapsulating structure (Stano and Luisi 2011). Although no such system has been built yet, the field is experiencing a notable progress, allowing to design more refined cell-like compartments (Stano 2019). In addition to the above-mentioned approaches, there is a third integrative strategy known as *middle-out* approach. Using it, scientists at the J. Craig Venter Institute (JCVI) were able to design, synthesize, and transplant into a pre-existing cell, the smallest genome of a free-living organism, generating *Mycoplasma mycoides* strain JCVI-syn3.0, the first semi-synthetic almost-minimal cell (Hutchison et al. 2016).

Research based on extant cells to define a hypothetical minimal cell is not related to the study of the origin of life because it is impossible to identify which one of the putative alternatives was adopted by primitive cells. In contrast, some *bottom-up* research programs are motivated by the possibility of better understanding this topic, by recreating some of the steps that precellular systems might have followed under primitive Earth conditions (Pereto and Catala 2007).

Definition

Cellular automata (CA) are dynamical systems in which space and time are discrete. A cellular automaton consists of an array of cells, each of which can be in one of a finite number of possible states, updated synchronously in discrete time steps, according to a local, identical interaction rule. The state of a ► [cell](#) at the next time step is determined by its own current state and the current states of a surrounding neighborhood of cells (Wolfram 1994).

Overview

Cellular automata were originally conceived by Ulam and von Neumann in the 1940s to provide a formal framework for investigating the behavior of

complex, extended systems (von Neumann 1966). In particular, von Neumann asked whether we could use purely mathematical-logical considerations to discover the specific features of automata that make them formally analogous with self-constructing and self-replicating biological systems.

Thanks to their simplicity and appeal, over the years, CA have been applied to the study of general phenomenological aspects of the world, including communication, computation, construction, growth, reproduction, competition, and evolution. CA have also been used successfully as an easy way to program models for studying phenomena of interest in several scientific fields, including physics, biology, and computer science.

Basic Methodology

As an example, let us consider the *parity rule* for a two-state, five-neighbor, two-dimensional CA. Each cell is assigned a state of 1 at the next time step if the combined parity of its current state and the states of its four neighbors in the *N*, *E*, *S*, and *W* directions is odd and is assigned a state of 0 if the parity is even. There are 32 different combinations for the states of the neighbors, including the central cell itself. The rule table consists of entries of the form.

This means that if the current state of the cell is 1 and the states of the north, east, south, and west cells are 0, 0, 1, 1, respectively, then the state of the central cell at the next time step will be 1 (because three bits in the neighborhood are in state 1). The rule is completely specified by the rule table given in Table 1. Fig. 1 demonstrates patterns that are produced by the parity CA.

The simplest CA are one dimensional with only two possible states per cell and a neighborhood constituted of the cell itself and its immediate right and left neighboring cells. Fig. 2 shows an example of the time evolution of an elementary CA.

Cellular Automata, Table 1 Parity rule table. CNESW denotes the current states of the center, north, east, south, and west cells, respectively. S_{next} is the state of the central cell state at the next time step

CNESW	S_{next}	CNESW	S_{next}	CNESW	S_{next}	CNESW	S_{next}
00000	0	01000	1	10000	1	11000	0
00001	1	01001	0	10001	0	11001	1
00010	1	01010	0	10010	0	11010	1
00011	0	01011	1	10011	1	11011	0
00100	1	01100	0	10100	0	11100	1
00101	0	01101	1	10101	1	11101	0
00110	0	01110	1	10110	1	11110	0
00111	1	01111	0	10111	0	11111	1

Cellular Automata, Fig. 1 Patterns produced by the parity rule, starting from a 20×20 rectangular pattern. White squares represent cells in state 0, and black squares represent cells in state 1. **a** After 30 time steps ($t = 30$), **b** $t = 60$, **c** $t = 90$, **d** $t = 120$

Cellular Automata, Fig. 2 A one-dimensional elementary CA is shown, where the horizontal axis depicts the configuration at a certain time t and the vertical axis depicts successive time steps (increasing down the page). The system starts in a randomly generated configuration of zeroes and ones

More formally, a cellular automaton A is a quadruplet:

$$A = (S, G, d, f)$$

where S is a finite set of states, G is the cellular neighborhood, $d \in \mathbb{Z}^+$ is the dimension of A , and f is the local cellular interaction rule, also referred to as the transition function.

Given the position of a cell $\mathbf{i}$, $\mathbf{i} \in \mathbb{Z}^d$, in a regular d -dimensional uniform lattice, or *grid* (i.e., $\mathbf{i}$ is an integer vector in a d -dimensional space), its *neighborhood* G is defined by

$$G_i = \{\mathbf{i}, \mathbf{i} + \mathbf{r}_1, \mathbf{i} + \mathbf{r}_2, \dots, \mathbf{i} + \mathbf{r}_n\},$$

where n is a fixed parameter that determines the neighborhood size and $\mathbf{r}_j$ is a fixed vector in the d -dimensional space.

The *local transition rule* f

$$f : S^n \rightarrow S$$

maps the state $s_i \in S$ of a given cell i into another state from the set S , as a function of the states of the cells in the neighborhood G_i .

Consider a one-dimensional CA with only two states $S = \{0, 1\}$. In this case, f is a function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ and the neighborhood size n is usually taken to be $n = 2r + 1$ such that

$$s_i(t+1) = f(s_{i-r}(t), \dots, s_i(t), \dots, s_{i+r}(t)),$$

where $r \in \mathbb{Z}^+$ is a parameter, known as the *radius*, representing the standard one-dimensional cellular neighborhood. Considering the $r = 1$ case, one obtains the so-called *elementary* CA, for which the neighborhood size is $n = 3$:

$$\begin{aligned} f: \{0, 1\}^3 &\rightarrow \{0, 1\}, s_i(t+1) \\ &= f(s_{i-1}(t), s_i(t), s_{i+1}(t)). \end{aligned}$$

In this case, the domain of f is the set of all 2^3 triplets, which gives rise to $2^8 = 256$ distinct elementary rules (Wolfram 1994). For finite-size grids, spatially periodic boundary conditions are frequently assumed, resulting in a circular grid. An example of an elementary rule has been shown in Fig. 2.

For a CA of size N , a *configuration* of the grid at time t is defined as

$$C(t) = (s_0(t), s_1(t), \dots, s_{N-1}(t)),$$

where $s_i(t) \in S$ is the state of cell i at time t . The progression of the CA in time is then given by the iteration of the *global mapping* F :

$$F: C(t) \rightarrow C(t+1), t = 0, 1, \dots$$

through the simultaneous application in each cell of the local transition rule f . The global dynamics of the CA can be described as a directed graph, referred to as the CA's *phase space* (Wolfram 1994).

Key Research Findings

Cellular automata have been proved to be universal computing devices and, as such, they can compute any computable function (Wolfram

1994). The question of whether cellular automata can model not only general phenomenological aspects of our world but also directly model the laws of physics themselves was raised by Fredkin and Toffoli (1982). A primary theme of this research is the formulation of computational models of physics that are *information preserving* and thus retain one of the most fundamental features of microscopic physics, namely, reversibility (Fredkin and Toffoli 1982; Margolus 1984; Toffoli 1980). This approach has been used to provide extremely simple models of common differential equations of physics, such as the heat and wave equations (Toffoli 1984) and the Navier-Stokes equation (Frisch et al. 1986). CA also provide a useful model for a branch of dynamical systems theory which studies the emergence of well-characterized collective phenomena, such as order, turbulence, chaos, symmetry breaking, and fractality, in discrete systems (Chopard and Droz 1998; Vichniac 1984).

Applications

For engineers and scientists, cellular automata are a particularly useful modeling device when the phenomenon to be studied does not lend itself to a clear mathematical model such as those represented by differential equations. In this case, simple local rules that are motivated by the phenomenon at hand may give rise to a global behavior that approaches that of the original system. Examples of this range from ► [chemotaxis](#), to snow transport by the wind, and to car traffic, just to name a few (Chopard and Droz 1998). Of course, how to choose the local cellular automata rules in order to produce the desired global behavior is a hard problem. It can be approached by trial and error or by heuristics such as evolutionary algorithms (Sipper 1997; Crutchfield et al. 2003) in which good rules evolve out of a population of possible candidate rules by the Darwinian principles of variation and selection. CA have thus been used as a simple and easy to implement model for studying phenomena of interest in several scientific fields, including physics, biology, engineering, and computer science.

Future Directions

In summary, CA suggest a new approach in which complex behavior arises in a bottom-up manner from nonlinear, spatially extended, local interactions and provide a simple and useful model for many complex systems arising in the sciences and in engineering.

CA exhibit massive parallelism, locality of cellular interactions, and simplicity of basic hardware components. As a consequence, in recent years, there has been a growing interest in the utilization of CA as actual embedded computing devices, e.g., in low-level vision, pseudorandom number generation, and cryptography (Chaudhuri et al. 1997). A trend that could become important in the future is the search for practical quantum computing CA devices, a concept that is potentially capable of revolutionizing computation and its applications; quantum cellular automata belong to this class (Pérez-Delgado and Cheung 2007).

History

The cellular theory was formulated after more than one and a half century of microscopic observations. Indeed, the invention of microscope during the seventeenth century offered new investigations to naturalists. For example, Robert Hooke (1635–1703) in his *Micrographia* (1665), Antoni van Leeuwenhoek (1632–1723), and Jan Swammerdam (1737–1780) observed microscopic objects: individual entities, often named animalcules, and parts of organisms. However, they did not have concepts to consider all these new observations. For example, it is important to notice that when Hooke used the word cell to name some little spaces that he had observed in vegetable organism, he did not expect to conceptualize anything, and his intention was only descriptive.

During all the eighteenth century, microscopic observations were more and more accurate. They showed a broad diversity of animalcules and microscopic structures in living beings. At the beginning of the nineteenth century, some theories claimed that there could be a unity in the microscopic structure. The French botanist Charles-François Brisseau de Mirbel (1776–1854) suggested that plants were constituted by a set of membranes with a lot of pores. A few years later, René Joachim Henri Dutrochet (1776–1847), who had discovered the osmotic phenomenon, claimed that cells constituted plants. However, in the wall of these cells, there could be some little globules that could be the fundamental entities. Then, François-Vincent Raspail (1794–1878) (one of the inventors of the microscopic colorations) considered that living beings were made of globules that were to be formed in the wall of other globules which would fit into each other. In that period, Lorenz Okenfuss (Oken) (1779–1851) claimed that living beings were a synthesis of infusorians. All these proposals have in common the fact that they are conceptions about the possibility of a microscopic and universal structure.

In 1838, the German botanist Matthias Schleiden (1804–1881) claimed that vegetable organisms were composed of cells in which there was a systematic structure, the cytoblast (which will be later named nucleus). Besides, Schleiden suggested that cells were the result of the accumulation of a liquid, the cytoblastem, between the cytoblast and the membrane. His colleague, Theodor Schwann (1810–1882), a specialist of animal physiology, generalized this theory to animals and indicated that the cytoblastem came from the interstitial fluid.

During the 1850s, Robert Remak (1815–1865) and Rudolph Virchow (1821–1902) independently (Remak in 1855 and Virchow in 1855–1858) asserted that every cell was the result of the division of a previous cell. From this time forth, the concept of cell has become central in biology.

During the end of the nineteenth century, the progress of microscopy led to observations of chromosomes and to the description of mitosis

(Fleming 1882) and meiosis (Boveri, Hertwig 1887–1892).

Synonyms

[Last universal common ancestor](#)

Definition

The cenancestor is the most recent ancestral species from which all extant living species have evolved. The idea that all present-day life is related by common ancestry was already suggested by Charles Darwin in *The Origin of Species* (1872). Nowadays, this hypothesis is strongly supported by the similarities at the biochemical and molecular levels of all organisms belonging to the three domains of life, i.e., Archaea, Bacteria, and Eukarya. The nature of this ancestral entity continues to be a matter of debate. Its level of complexity (in number of genes), the chemical nature of its genome (whether DNA or RNA), or its prokaryotic-like nature have been discussed along other aspects of its biology.

The Centaurs are outer ► [asteroids](#) whose orbits are mostly confined between those of Jupiter and Neptune. Due to giant planets' perturbations, these objects have transient orbits with typical lifetimes of a few million years. There are a few hundreds of Centaurs presently known, among them (2060) Chiron (also named 95P/Chiron), (5145) Pholus, and (10199) Chariklo, the biggest Centaur found to date with a diameter of 260 km. Saturn's satellite Phoebe is believed to be a captured Centaur. This population appears to be intermediate between asteroids and ► [comets](#), as any Centaur coming close enough to the Sun is expected to show cometary activity. The total number of Centaurs of size above 1 km in diameter is estimated to be above 40,000 objects.

Center of Mass Velocity

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Synonyms

[Barycenter velocity](#)

Definition

The center of mass velocity of a system of massive points or objects is the velocity of the point where the resultant force of gravitational attraction acts. The system's whole mass can be considered to be concentrated at this point, for the purpose of calculations. The motion of the center of mass of an object in free fall is the same as the motion of a point object located there.

Ceres

Ralf Jaumann

Institute of Geological Sciences, Planetary Sciences and Remote Sensing, Freie Universität Berlin, Berlin, Germany

Keywords

Asteroid · Dwarf planet

Definition

Discovered in 1801 by Giuseppe Piazzi, 1 Ceres is the largest and one of the oldest and most intact objects in the asteroid belt, cataloged by the IAU as a ► [dwarf planet](#) in 2006. Ceres orbits the ► [Sun](#) at a distance of 2.76 AU and differs from any other ► [asteroid](#) visited so far. Its surface is covered with ► [clay](#), a hydrated ► [rock](#) alteration product, and also shows water ice frost in the regolith. This is consistent with thermal models making Ceres an icy object that has been subject to differentiation and hydrothermal activity and that hosts a liquid brine-like subsurface layer even today with evidence for cryovolcanism. The NASAs Dawn spacecraft orbited Ceres for 3.5 years from 2015 to 2018.

Overview

1Ceres (Fig. 1) is an oblate spheroid with a best-fitting ellipsoidal shape of $483.1 \times 481.0 \times 445.9 \pm 0.2$ km, a mass of $(938.416 \pm 0.013) \times 10^{18}$ kg, a density of

$2162 \pm 0.0008 \text{ kg/m}^{-3}$ (Park et al. 2016), a rotation period of 9.074170 ± 0.000001 h, and an orbital period of 4.6 years (Thomas et al. 2005; Russell et al. 2016; Konopliv et al. 2018). Ceres is classified as a C- or G-type asteroid, sharing similarities with carbonaceous chondrites. The physical properties of Ceres are consistent with a differentiated structure of a rocky core, a thick wet outer ► [mantle](#) containing ► [water](#) ice and brines and a desiccated surface (Russell et al. 2016). Its surface temperatures vary with latitude from 130 K at the poles to 180 K at the equator, reaching a maximum of 235 ± 4 K (Li et al. 2006; Tosi et al. 2015). The surface single scattering ► [albedo](#) varies from 0.094 to ~ 0.11 with the bright spot in Occator crater reaching 0.67 to 0.80 (Li et al. 2016). Ceres' surface is heavily cratered, but due to the weak interior, larger craters are morphologically relaxed. Ceres has a mechanically strong lithosphere with a weaker deep interior implying Ceres' icy shell to be in ► [hydrostatic equilibrium](#) (Russell et al. 2016; Buczkowski et al. 2016). The gravity field is consistent with a rigid crust floating on a more liquid substratum-balancing deficiency, so-called Airy isostatic compensation, limiting Ceres' crustal density to be between 1200 and 1600 kg/m^3 with mean crustal thickness between 27 and 43 km (Konopliv et al. 2018). Ceres' dry surface displays hydroxylated silicates, including ammoniated clays (Russell et al. 2016). The spectral analysis yields a composition of the surface of a dark component (carbon, magnetite?), Mg-phyllosilicates, ammoniated clays, carbonates, and salts indicating extensive water-related processes, chemical differentiation, and endogenous, global-scale aqueous alteration (De Sanctis et al. 2018). Sodium carbonates have been identified in several areas on the surface, notably in Occator bright faculae (De Sanctis et al. 2018). Organic matter has also been discovered in several places, most conspicuously in a large area close to the Ernutet crater (De Sanctis et al. 2018). The presence of abundant volatiles at depth is supported by geomorphologic features such as flat crater floors with pits, lobate flows of materials, and a singular mountain that appears to be an extrusive cryovolcanic dome (Buczkowski et al. 2016; Ruesch et al. 2016). Ahuna Mons (Fig. 2) is a

Ceres, Fig. 1 Dawn took this image during its third extended-mission science orbit (XMO3) in February 2017, from about 7500 kilometers above the surface of Ceres. Occator crater with the central white dot is 92 km in diameter. Ahuna Mons appears at the limb lower right as small mountain against the dark sky (NASA/JPL-Caltech/UCLA/MPS/DLR/IDA). https://photojournal.jpl.nasa.gov/jpegMod/PIA11240_modest.jpg

Ceres, Fig. 2 Ceres' cryovolcano, Ahuna Mons, in perspective view. The spacecraft's framing camera took the images from Dawn's low-altitude mapping orbit, from an altitude of 385 km in August 2016. The mountain is 4 km high (NASA/JPL-Caltech/UCLA/MPS/DLR/IDA). <https://photojournal.jpl.nasa.gov/catalog/PIA20915>

~17-km-wide and 4-km-high mountain. Its summit topography is concave downward, and its flanks are at the angle of repose. The morphology is characterized by troughs, ridges, and hummocky areas at the summit, indicating multiple phases of activity, such as down-slope lineations on the flanks, due to rock-falls and accumulation of slope debris (Ruesch et al. 2016). Ahuna Mons is a volcanic dome of extruded material of high viscosity with recent activity within the past 210 ± 30 million years (Ruesch et al. 2016). Similar cryovolcanic activity occurs in the Occator impact crater. Cryovolcanism on Ceres is due to hydrated salts with low eutectic temperatures and low thermal conductivities enabling the presence of cryomagmatic hydrothermal brine-related liquids (Russell et al. 2016; De Sanctis et al. 2018).

Cerium, Anomalies of

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

Cerium (Ce) is the second rare-earth element (REE) in the periodic table, most of which are trivalent at the conditions prevalent in the mantle, the crust, and planetary surfaces. In the modern ocean, the redox boundary between trivalent and tetravalent Ce is close enough to the O_2 – H_2O equilibrium that a substantial fraction of this element is oxidized and rapidly scavenged by Fe and Mn oxides. Excess Ce with respect to adjacent REE La and Pr is common in Mn nodules and encrustations, which leaves seawater, phosphates, and carbonates with a deficit. Cerium anomalies in sediments and sedimentary rocks are useful proxies for the state of oxidation in the ocean and the atmosphere in the past.

Chalcophile Elements

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

In the Berzelius-Goldschmidt classification, *chalcophile elements* are elements with a low affinity for oxygen and which preferentially bond with sulfur to form sulfides. Their name derives not from sulfur but from copper, which also forms sulfides. This group comprises transition elements (Cu, Zn, Cd, Ag, Hg), heavy metals (Ga, In, Sn, Pb, Po, Bi, Tl), and metalloids (Ge, S, Sb, Se, Te, As). As a consequence of their relatively low condensation temperatures (500–1,100 K), most of these elements are depleted in terrestrial planets with respect to chondrites.

Chance and Randomness

Francesca Merlin

CNRS UMR 8690 IHPST & Université Paris 1, Paris, France

Keywords

Chance · Determinism · Indeterminism · Probability · Randomness · Unpredictability

Synonyms

[Haphazardness](#); [Indeterminacy](#); [Stochasticity](#); [Uncertainty](#)

Definition

Chance and randomness are usually considered as synonymous; however, they can have different meanings, in several scientific fields as in everyday contexts. In particular, chance has a broader scope than randomness, the latter being often interpreted according to more specific mathematical connotations. Broadly speaking, both are used to qualify events that are unpredictable in the sense that they have no particular aim or direction (unbiased events) and that they occur in an irregular and disordered (haphazard) way which makes it difficult to make money betting.

Overview

Chance is a double-faced notion including subjective chance, which concerns our knowledge of real events, and objective chance, which refers to an inherent property of the structure of the world, independently of our knowledge. Chance and randomness are often used as counterparts to determinism: a random process is said to be nondeterministic in the sense that, from a set of starting conditions, it can produce different outcomes according to some law of probability. However, neither notion is necessarily incompatible with the assumption of determinism. Subjective chance, when defined as ignorance of the real underlying causes, implies that there is no chance in the real world, but for human knowledge: for instance, we might assign a 50% chance to both possible outcomes of the flip of a fair coin (“heads” and “tails”) because we ignore the underlying causes (e.g., the way the coin is flipped). This recalls the Laplacian notion of chance, which is a deterministic notion; nevertheless, subjective chance is also compatible with indeterminism in so far as the underlying causes that we do not know about might still be the result of an indeterministic process. Objective chance can refer to an event that is not planned (or by design), as in Aristotle’s accidental meeting with the person who owed him money. This notion implies the confluence of two or more independent causal chains: in this sense, Cournot claimed that the fact that two brothers

serving in different armies died the same day is a matter of chance. Chaotic processes provide an example of chance as sensitivity to initial conditions in the sense that small differences in initial conditions may yield radically different outcomes. Whereas all notions of chance mentioned above are noncommittal to determinism nor indeterminism, this is not the case for chance according to the Copenhagen interpretation of quantum mechanics, according to which indeterminism is considered a true description of the microlevel world. Randomness mostly has a mathematical connotation, like in algorithmic information theory where a binary sequence is said to be Kolmogorov random if and only if it is incompressible, i.e., it is shorter than any computer program that can produce it. Other formal definitions of a random sequence (e.g., Martin-Löf’s) have been recently formulated, each of which tries to capture our intuitive notion of randomness.

Chandrasekhar's Limit

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Chandrasekhar's limit, named after the Indian astrophysicist Subrahmanyan Chandrasekhar, is a critical mass of about 1.4 solar masses that the core of a ► [star](#) can attain, before collapsing to become a neutron star or a black hole. This core is built from the heavy elements that the star synthesizes during its lifetime through nuclear fusion. This limit is thus the maximum mass of a stable ► [white dwarf](#) star. Beyond this critical mass, the relativistic electron degeneracy pressure is unable to counteract the gravitational forces. Stars with mass higher than eight solar masses develop a degenerate core, whose mass will grow until it exceeds this limit, leading to a ► [supernova](#) explosion.

²Centro de Biología Molecular Severo Ochoa,
Universidad Autónoma de Madrid, Madrid, Spain

Keywords

Water stress · Mg_2Cl · LiCl , Ethanol · Urea ·
Phenol · Hydrogen bonds

Definition

Chaotropy is the disorder exerted by chaotropic agents on cellular macromolecular interactions.

Overview

Chaotropes are compounds that destabilize the secondary structure and the folding of biomolecules by replacing the water in the hydration shells, affecting the hydrogen bonds or penetrating in the hydrophobic areas. These compounds entropically disorder cellular macromolecules, via a chaotropy-mediated mode of action, inducing cellular water stress. Whereas this stress is independent of osmotic stress, it can occur concomitantly with osmotic stress. On the contrary, kosmotropes are compounds that favor the formation of stronger intermolecular hydrogen bonds than those formed between water molecules themselves. As a result, biomolecules become more rigid and their interactions more stable. Recent studies elaborate the reasons why chaotropy and kosmotropy refer to the entropic effects of substances on the biomolecules system rather than the solvent per se. Whereas parameters such as temperature, pressure, pH, hydrophobicity, and water activity can be quantified via standard scales of measurement, the chaotropic/kosmotropic activities of environmentally ubiquitous substances have no widely accepted, universal scale. Hallsworth and collaborators developed a method to compare the chaotropy and kosmotropy of different compounds using an agar-gelation assay. Ethanol, urea, MgCl_2 , LiCl , and phenol are well-known chaotropic agents, while NaCl , KCl , and NH_4SO_4 exhibit a potent kosmotropic activity. Knowing the natural existence of chaotropic and kosmotropic agents in the environment, it is considered of interest to know how their presence affects the development of microorganisms, regulating the interaction between macromolecules. Some natural environments, like the hypersaline anoxic lakes of the Mediterranean Ridge and Don Juan Pond (Antarctica) or Salar de Uyuni (Bolivia),

are well-known chaotropic model systems due to the detection of high concentrations of MgCl_2 and LiCl . Considering that (i) chaotropy is an important factor searching for the limits of life, (ii) that kosmotropic agents could buffer the negative effect of chaotropy, and (iii) the high concentration of chaotropic salts is detected on Mars and other bodies of the Solar System, it is considered a subject of interest in astrobiology.

Charon

Tanguy Bertrand and Emmanuel Lellouch
Laboratoire d'Etudes Spatiales et
d'Instrumentation en Astrophysique (LESIA),
Observatoire de Paris, CNRS, Meudon, France

Keywords

Pluto system · Dwarf planet · Trans-neptunian object

Definition

Charon is the largest moon of Pluto and a massive Kuiper Belt object (currently the sixth largest

known trans-neptunian object). It was visited for the first time by the New Horizons spacecraft during its flyby of the Pluto system on July 14, 2015, which allowed for detailed observation of its surface. The name *Charon* refers to the Greek mythological figure who guided souls across the River Styx in the kingdom of Hades, which in Roman mythology corresponds to Pluto. James W. Christy, who discovered Charon, also suggested this name as a scientific-sounding version of his wife Charlene's nickname, "Char."

Overview

Discovery and Early Characterization

Charon was discovered on June 22, 1978, by Christy, who noticed that the available (astrometric-aimed) images of Pluto presented a slightly elongated shape with variable orientation that could be explained if there was another object periodically orbiting Pluto but not distant enough to be fully resolved. Charon's existence was indisputably proven when the Pluto-Charon system entered a period of mutual eclipses and transits in 1985–1990. In the 1990s, the Hubble Space Telescope imaged both Pluto and Charon as separate disks (their maximum separation is ~ 0.9 arcseconds, and Charon's apparent size is ~ 0.05 arcseconds).

Mass, Size, and Internal Structure

Charon's diameter is 1212 ± 6 km, just over half that of Pluto's, and larger than the dwarf planet Ceres. Its mass is 12.2% that of Pluto's, and its density is 1.702 ± 0.021 g/cm³, slightly lower than that of Pluto (1.860 ± 13 g/cm³). This suggests that Charon is made of 55% rock and 45% water ice whereas Pluto is about 70% rock, and supports the idea that Charon was created from Pluto's icy mantle material by a giant impact (see "[Formation](#)" below).

Orbital and Spin Parameters

Charon orbits Pluto at a distance of 19,590 km or ~ 17 Pluto radii, making it 20 times closer to it than Earth's Moon is to Earth. With a mass ratio of

about 8, the system barycenter is outside of Pluto, and consequently the Pluto–Charon system can be thought of as a dwarf double planet system, as both bodies rotate around the system's center of mass.

As the result of full tidal evolution, the two objects are gravitationally locked, and therefore always show the same face to each other, with a mutual rotational period of 6.387 days.

Surface Appearance and Geology

Charon is geologically simpler than Pluto, and appears more similar to some of the icy moons of Saturn and Uranus, having a water-ice-dominated, ancient cratered surface that preserves an early history of tectonism and resurfacing, likely completed within the first billion years of Solar System history.

Charon's main geological features are (1) extensive smooth plains with few craters, providing evidence of effusive cryovolcanism (resurfacing flows), and (2) aligned tectonic features including up to 12 km-deep faulting systems and canyons at the equator (most prominently Serenity Chasma that extends over ~ 1000 km). These are indicative of an early internal liquid water ocean (~ 40 km thick according to models), whose freezing would have produced global expansion of the crust as ice replaced higher-density liquid water and formation of the faulting systems. The absence of compressional features provides strong evidence that Charon is differentiated. Some regions of Charon, e.g., Vulcan Planitia and Oz Terra, are relatively heavily cratered (comparable to the most cratered regions on Pluto), indicating ages older than 4 Ga.

Surface Color, Composition, and Temperature

Charon's surface has a mean geometric albedo of 0.38, and presents a latitudinal albedo trend with a bright equator band and darker poles, with a factor of ~ 2 contrast on global scale. In relation to its darker mean albedo and smaller thermal inertia than Pluto, Charon's dayside mean surface temperature (~ 55 K) is higher than Pluto's.

Unlike Pluto, Charon's surface lacks volatile ices and appears to be dominated by water ice,

with the presence of ammonia-bearing species near specific impact craters only, suggesting that the bulk of the resurfacing flows are water ice rich.

The north polar region, called Mordor Macula, is distinctly red, likely due to solid hydrocarbons formed by condensation of methane gas that escaped from Pluto's atmosphere and subsequent processing by UV photolysis and energetic radiation. This scenario requires Charon's poles to reach temperatures <25 K during polar night, for methane to be stably cold-trapped.

As expected in relation to the lack of surface volatiles, Charon appears to have little, if any, atmosphere, with upper limits of at most 0.3 nanobar for a variety of compounds and as low as 4 picobar for N_2 .

Formation

As has long been recognized, the angular momentum of the Pluto-Charon binary system is best explained by a giant impact between comparably sized bodies that occurred during the early history of the Solar System. This scenario, similar to that explaining the origin of Earth's Moon, is now supported by hydrodynamic simulations, in which Charon forms either "intact" or through accumulation from a disk produced by the collision, which can also account for the formation of Pluto's other small moons. Favored cases include oblique, low-velocity impacts, but there are a range of solutions in terms of the possible internal structures (differentiated or not) of the pre-impact bodies.

Chassignites

Ana-Catalina Plesa

Institute of Planetary Research, German
Aerospace Center (DLR), Berlin, Germany

Keywords

SNC meteorites · Isotopic ratio · Cosmic-ray
exposure age · Noachian · Amazonian

Definition

Chassignites are a subgroup of the SNC meteorites named after the first sample found, the Chassigny meteorite. These dunitic samples (more than 90% olivine) are classified as olivine-chromite cumulate rocks.

Overview

This subgroup of the Martian meteorites contains three samples: Chassigny, NWA 2737 (field name “Diderot”), and NWA 8694 (Udry et al. 2020).

The crystallization ages of the samples have been determined to lie around 1.3 Ga, corresponding to middle Amazonian epoch (Bogard and Garrison 1999; Nakamura et al. 1982; Nyquist et al. 2001), similar to the nakhlites crystallization age. The similarity with the crystallization history of the nakhlites and a nearly identical initial $^{87}\text{Sr}/^{86}\text{Sr}$ isotopic ratio led first to the conclusion that both the chassignites and the nakhlites may sample different sites of the same or similar igneous complexes (Nakamura et al. 1982). Moreover, the similar cosmic-ray exposure age (11.1 ± 1.6 Ma) implies that they all have been ejected in one event (Nyquist et al. 2001). However, their rare earth elements (REE) abundances indicate that they have not crystallized from the same magma (Longhi 1991; Wadhwa and Crozaz 1994). Harvey and Hamilton (2005) proposed the northeast region of Syrtis Major volcanic complex to be a possible site for the ejection of chassignites. Although some sites, for example, Nili Fossae, that were proposed as

source terrains for chassignites are of Noachian age, the olivine-bearing regions within these terrains could be much younger.

Chassigny

Ana-Catalina Plesa

Institute of Planetary Research, German
Aerospace Center (DLR), Berlin, Germany

Definition

Chassigny is a 4-kg Martian meteorite found in 1815 in Chassigny, France. It names the SNC subgroup containing also the NWA 2737

(Diderot) and the NWA 8694 samples. *Chassigny* is a dunitic sample (more than 90% olivine), classified as an olivine-chromite cumulate rock, for which a crystallization age has been determined to lie around 1.36 Ga, similar to the nakhlites age. Spectral signatures matching the mineralogy of *Chassigny* have been identified in Nili Fossae near Syrtis Major, southwestern region of Isidis rim, in the Ganges and Eos Chasmata, within craters southwest of the Ganges Chasma, and in the northeastern part of the Hellas basin rim. Although some candidate sites like Nili Fossae have an old Noachian age, the olivine-bearing materials located within could be much younger.

Chemical Bistability

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Chemical bistability in astrochemistry refers to the existence of multiple steady states known to occur in chemical models of molecular abundances in dense interstellar clouds. For certain combinations of model (control) parameters (cosmic ray ionization rate, elemental abundances, etc.), three steady states can appear, comprising two stable states connected by an unstable one, i.e., the solutions exhibit hysteresis.

History

Chemical bistability in astrochemical models was first positively identified by Le Boulrot et al. (1993).

Acronyms

Chemobrionics

Definition

Chemical gardens are mineral biomorphic structures produced by self-organizing nonequilibrium

processes during which a metal-salt acts as a seed for the irreversible precipitation of a large panel of anions (silicate, phosphate, carbonate, and others). Generally, the process involves the following step: (a) formation of a semipermeable metal/anion hydrate membrane; (b) osmotic expansion and rupture of the initial membrane; and (c) growing of a bilayered biomorphic structure (composed by external anion-rich layer and internal metal oxide-rich layer) (Cartwright et al. 2002). Chemical gardens can fuel prebiotic chemistry transformations due to the generation of ionic and pH gradients across the membrane (Glaab et al. 2021). Representative examples are the syntheses of prebiotically relevant compounds, such as amino acids, nucleic acid bases, and carboxylic acids, from formamide and metal salts in the presence of alkaline (pH 12) sodium silicate solutions (Saladino et al. 2016; Bizzarri et al. 2018). In these reactions, a different selectivity was observed in association with the occurrence of the compartmentalization process, nucleic acid components being mainly confined inside the membrane (Saladino et al. 2019). In addition, amino acids affect chemical garden growth and morphology by their preferential accumulation outside the membrane (Hooks et al. 2020). These results provide an example of how an inorganic process can favor the synthesis and compartmentalization of biologically relevant molecules playing a different role in the emergence of life.

Chemical Reaction Network

Raphaël Plasson

Department of Earth and Planetary Science,
Harvard University, Cambridge, MA, USA

Keywords

Metabolism · Stoichiometric matrix

Synonyms

Automaton, Chemical; Chemical system;
Reaction network

Definition

A chemical reaction network is a set of chemical compounds (being the network nodes) connected by a set of chemical reactions (being the network vertices).

Overview

A chemical system is a set of chemical compounds that are involved in a set of chemical reactions. Formally, this can be described as a network, where each compound is connected with each other by the corresponding chemical transformations; each chemical compound is then a node of the network, while each chemical reaction is a directed vertex of the network, connecting the involved chemical compounds, from the reactants towards the products. The purpose is to study this system as a whole, rather than solely considering it as the sum of its different elements.

A reaction network is typically described by its stoichiometric matrix v . The $v_{i,j}$ element is the stoichiometric coefficient of the compound i in

the reaction j , i.e., the number of molecule of i that is involved in the reaction j . This number is by convention negative for the reactants (that are disappearing) and positive for the products (that are formed). The mathematical analysis of this matrix gives information about the structure of the reaction network (Schilling et al. 2000). The identification of matter fluxes and of patterns of mass conservation leads to the description of the reaction network in terms of transformation pathways (Papin et al. 2004) and of conserved moieties (Schuster and Hilgetag 1995). This mathematical analysis only gives static information about the reaction network. Adding the kinetic data relative to each chemical reaction allows establishment of the set of ordinary differential equations (ODE) describing the reaction network. Its numerical integration gives the dynamical behavior of the system (Alves et al. 2006).

The description of chemical reaction networks is used in very different fields, dealing with chemical complexity. This is typically the case of biosystems, especially for the description of ► **metabolism** (Schuster and Hilgetag 1995; Schilling et al. 2000; Papin et al. 2004; Metabolism databases), but also in abiotic systems as in astrochemistry (Woodall et al. 2007), combustion modeling (Manion et al. 2008), etc. The precise description of these complex chemical systems generally relies on the existence of extensive databases, summing up thermodynamic and kinetic data.

In the field of astrobiology, ► **prebiotic chemistry** can be seen as a bridge between ► **abiotic** and biotic chemical reaction networks. The purpose is to understand how a reaction network consisting of very simple compounds can spontaneously evolve into a more complex and structured network, and how complex behaviors can emerge from the association of several simple reactions (e.g., network ► **autocatalysis**, energy coupling, self-replication, etc.) (Wagner and Ashkenasy 2009).

Chemocline

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the
Earth System, Université du Québec à Montréal,
Montréal, QC, Canada

Definition

The chemocline is the vertical chemical gradient or cline, which is produced in a mass of water

having restricted circulation (e.g., meromictic lakes where water layers do not intermix). Local conditions of circulation provoke the formation of bottom anoxic waters – where only anaerobic organisms exist – overlain by oxygenated waters, where aerobic photosynthetic life flourishes. At the contact between these two zones, photosynthetic communities of anaerobic purple sulfur bacteria develop, taking advantage of both the sunlight from above and the hydrogen sulfide (H_2S) produced below. In astrobiology, this zone of the chemocline is studied because it could be an analogue of Archean niches of life where limited oxygenated waters developed over an anoxic Archean ocean.

Chemolithotroph

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Keywords

Chemolithotrophy

Definition

A chemolithotroph is an organism that is able to use inorganic reduced compounds as a source of energy. This mode of metabolism is known as chemolithotrophy.

History

Chemolithotrophy was discovered by Winogradsky while studying the microorganisms involved in the oxidation of sulfur compounds.

Overview

Chemolithotrophy is found only in prokaryotes and is widely distributed among Bacteria and Archaea. The spectrum of inorganic compounds that can be used as electron donors by chemolithotrophs is rather broad (H_2S , S^0 , $\text{S}_2\text{O}_3^{2-}$, H_2 , Fe^{2+} , NO_2^- , or NH_3). Some microorganisms are rather specific regarding the inorganic substrates they can use to generate energy, while others are able to use different compounds (versatile). The best characterized chemolithotrophs are aerobic respirers, which use oxygen as the ► [electron acceptor](#), although the list of chemolithotrophs capable of employing ► [anaerobic respiration](#) is increasing rapidly. Chemolithotrophs have ► [electron transport](#) systems similar to those of chemoorganotrophs, which are used for the generation of a ► [proton motive force](#). The only difference is that chemolithotrophs donate electrons directly to the electron transport chain, while chemoorganotrophs must generate cellular reducing power (NADH) from the ► [oxidation](#) of reduced organic compounds, which is then used to donate electrons to the electron transport system. This proton motive force is used to generate ATP or any cellular functions that might require this type of energy (active transport, movement, etc.). An important distinction between chemolithotrophs and chemoorganotrophs is their source of carbon. Chemoorganotrophs use organic compounds as both energy and carbon sources, while chemolithotrophs are generally autotrophs (with few exceptions, known as mixotrophs, that use reduced organic compounds as a source of carbon). Chemolithotrophs can obtain the reducing power needed to assimilate CO_2 directly from the inorganic substrate (only H_2 oxidizers) or by the reverse electron transport reaction (the rest of chemolithotrophs), in this case using proton motive force as a source of energy.

Hydrogen is a common product of geochemical reactions and microbial metabolism, and a number of chemolithotrophs are able to use it as an electron donor in energy metabolism. A wide variety of anaerobic H_2 -oxidizing Bacteria and

Archaea are known, differing in the electron acceptor they use (nitrate, sulfate, ferric iron, etc.).

The most common sulfur compounds used as electron donors are hydrogen sulfide (H_2S), elemental sulfur (S^0), and thiosulfate ($\text{S}_2\text{O}_3^{2-}$). The final product of sulfur oxidation is sulfate (SO_4^{2-}), although an intermediate step is the formation of elemental sulfur, which in some cases is stored as an alternative source of energy. One of the products of sulfur oxidation reaction is the generation of protons (H^+); consequently, one result of the oxidation of reduced sulfur compounds is the acidification of the environment by the production of sulfuric acid.

The aerobic oxidation of ferrous iron (Fe^{2+}) to ferric ► [iron](#) (Fe^{3+}) is an energy-yielding reaction, used by some prokaryotes to conserve energy. Only a small amount of energy is generated by this reaction; thus, iron-oxidizing microorganisms must oxidize large amounts of reduced iron to grow. Ferrous iron is oxidized very rapidly in the presence of oxygen, while it is very stable at acidic conditions. This is probably the reason why many iron-oxidizing microorganisms are acidophilic. Despite the instability of ferrous iron at neutral pH, there are a number of iron-oxidizing bacteria that can thrive at circumneutral pH. Some anoxygenic phototrophic bacteria can use ferrous iron as a source of environmental reducing power. Recently, it has been shown that some denitrifying bacteria can anaerobically respire (oxidize) reduced iron. The use of ferrous iron to obtain energy is widely distributed in nature, a property that was ignored until recently, due to thermodynamic considerations.

The most common nitrogen compounds used as electron donors for energy conservation are ammonia (NH_3) and nitrite (NO_2^-). Both compounds can be oxidized aerobically by chemolithotrophic nitrifying bacteria. Some nitrifying microorganisms oxidize ammonia to nitrite, while another group oxidizes nitrite to nitrate. For many years, the complete oxidation of ammonia required the concerted activity of these two types of microorganisms, but recently it has been shown that bacteria from the *Nitrospira* genus can oxidize ammonia to nitrate (Comammox). A special case of nitrogen-oxidizing microorganisms

corresponds to those capable of carrying out the anoxic oxidation of ammonia, a process known as Anammox. In this case, the electron acceptor is nitrite, and the product of the metabolic reaction in addition to proton motive force is the generation of N_2 . This metabolic reaction is carried out by a special type of microorganisms belonging to the Planctomycetes phylum of Bacteria.

Due to their metabolic properties, chemolithotrophs are of astrobiological interest and also critical elements of the ► [biogeochemical cycles](#).

Chemoorganotroph

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Keywords

Fermentation · Heterotrophs · Respiration

Definition

A chemoorganotroph is an organism that obtains energy from the oxidation of reduced organic compounds. The list of compounds from which chemoorganotrophic organisms can generate energy and their sources of carbon is very long, making these microorganisms extremely versatile. Two mechanisms for energy conservation are known for chemoorganotrophs: ► [fermentation](#) and ► [respiration](#). In the case of fermentation,

cellular energy in the form of ATP is obtained by cytoplasmatic soluble catalytic reactions involved in substrate-level phosphorylation. In the case of respiration, ATP is produced at the expense of the ► [proton motive force](#) resulting from coupling the substrate oxidation reactions via the generation of reducing power to the electron transport chain. Due to their type of metabolism, chemoorganotrophs are fundamental elements of the carbon cycle.

Chemotaxis

Irma Marín
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Ciudad
Universitaria de Cantoblanco, Madrid, Spain

Keywords

Motility · Two-component system

Definition

Chemotaxis is the process by which motile bacteria sense changes in their chemical environment and move to more favorable conditions.

Overview

Bacteria, Archaea, and some eukaryotes use two-component signaling pathways to detect environmental conditions and bring about appropriate changes in cellular behavior. This process has been studied in *Escherichia coli* over the past 40 years.

E. coli has several flagella per cell (4–19) that can rotate in two ways: counterclockwise (CCW) that aligns the flagella causing the bacterium to swim in a straight line and clockwise (CW) that causes the bacterium to tumble since each flagellum rotates independently.

Bacteria monitor chemical concentrations using multiple transmembrane receptors, named methyl-accepting chemotaxis proteins (MCPs). Five MCP-mediating responses to specific attractant and repellent stimuli have been reported in *E. coli*: Tar, Tsr, Trg, Aer, and Tap. The signals from these receptors are transmitted across the cell membrane into the cytoplasm, where Che proteins (CheA, CheB, CheW, CheY, CheR, and CheZ) are activated.

Signals from the receptors are received by the CheA histidine kinase. CheA is coupled to transmembrane receptors (MCP) by the adaptor protein CheW. The activation of the receptor causes autophosphorylation of CheA that also phosphorylates CheB and CheY. CheY~P binds then to the flagellar motor protein FliM, inducing a change from CCW to CW rotation of flagella, thus increasing the frequency of tumbles of the bacterium (Fig. 1).

A feedback mechanism that modulates the methylation level of the MCP receptors controls adaptation. Two enzymes, CheB and CheR, are involved in this mechanism by interacting with the receptor and chemically modifying them.

CheB, activated by CheA, acts as a methylesterase that removes methyls from the cytoplasmic part of the receptor. It works antagonistically with CheR, which is a methyltransferase. The higher the amount of methylated residues of the receptor, the lower the sensitivity to stimuli. The result is an enhancement of CheA autophosphorylation and, thereby, transmission of a CW signal. When an attractant generates a signal, demethylation of the receptor is induced, closing the feedback loop.

The system is continuously adjusted to environmental chemical levels, remaining sensitive to small changes even under extreme chemical concentrations, since the system compares concentrations along the movement path. When necessary this is switched to go closer to or further away

Chemotaxis, Fig. 1 Model of chemotaxis mechanism as described in the text. A, B, R, W, Y, and Z are CheA, CheB, CheR, CheW, CheY, and CheZ proteins, respectively

from a higher concentration of attractant or a repellent, respectively. Other mechanisms are involved in increasing the absolute value of the sensitivity on a given background. *E. coli*, but not *B. subtilis*, possesses the protein CheZ that enhances the rate of CheY dephosphorylation.

Definition

Chemotrophs are organisms that obtain energy by the oxidation of reduced compounds. The

substrates used by chemotrophs can be organic (organotrophs) or inorganic compounds (lithotrophs). According to the carbon source, chemotrophs can be either chemoautotrophs or chemoheterotrophs. Because chemoheterotrophs use reduced organic compounds as a source of energy and a source of carbon, they are usually called heterotrophs, although the term is misleading because, strictly, it only refers to the carbon source. Chemoautotrophs use inorganic energy sources and are known as chemolithoautotrophs or lithoautotrophs. Chemolithoheterotrophs are a special kind of chemotroph that use inorganic compounds as an energy source and reduced organic compounds as a carbon source. They are known as mixotrophs. Chemotrophs use ► [fermentation](#) and ► [respiration](#) to obtain energy. Fermentation is restricted to organotrophs.

CHEOPS

Michel Viso
Innovaxiom, Paris, CX, France

Keywords

Exoplanet · Transit

Definition

The CHaracterizing ExOPlanet Satellite (CHEOPS) is a small mission selected by the

European Space Agency (ESA) in October 2012 and then adopted in February 2014. It is the first mission dedicated to analyze exoplanet ► [transits](#) by means of ultrahigh precision photometry on bright stars already known to host planets. It provides the unique capability of determining accurate radii for a subset of planets with a size ranging from Earth to Saturn which orbit bright stars and for which the mass has already been estimated from ground-based spectroscopic surveys. The knowledge of mass and diameter allows to derive the precise density and then to draw hypotheses about the composition of these planets. The 250 kg satellite is equipped with a 32 cm telescope. The payload is developed under the responsibility of the University of Bern (Switzerland). Cheops was launched December 18, 2018, in a sun-synchronous orbit at about 700 km. Its lifetime is set at 3.5 years. Recently Cheops has revealed that an exoplanet orbiting its host star within a day has an ovoid shape more like that of a rugby ball than a sphere. The detection, for the first time, of such a deformation offers new insights into the internal structure of this kind of planets.

Definition

Chert is a microcrystalline rock consisting almost exclusively of silica. Chert may occur as

stratiform units, occasionally with laminar alteration of colors (red, white, black, green), in dikes crosscutting the stratigraphy, or as nodules in carbonates. Some stratiform cherts in Archean ► [greenstone belts](#) are among the earliest sedimentary rocks and preserve the oldest evidence for life (► [Apex Chert](#), ► [Pilbara Craton](#), Western Australia).

History

The oldest preserved chert units occur in the highly metamorphic and deformed 3.6–3.7 Ga supracrustal units of the ► [Isua Supracrustal Belt](#) in West Greenland (Nutman et al. 1984). The Isua cherts may have had a sedimentary origin or may represent volcanic rocks that were hydrothermally altered and layered as a consequence of intense plastic deformation (Nutman and Friend 2009; Polat and Frei 2005). Trace elements indicate that the chert/► [banded iron formation](#) units have seawater-like signatures suggesting at least a component of sedimentary origin as a marine chemical precipitate.

In both the ► [Pilbara](#) (Australia) and the Barberton (South Africa) Greenstone Belts, the oldest well-preserved volcanic sequences which contain stratiform chert units (Byerly et al. 1996; Van Kranendonk et al. 2002) formed between ~3.57 and ~3.30 Ga. Despite the good preservation of the greenstone sequence, the origin of the stratiform chert units is still controversial. van den Boorn et al. (2007) distinguished three different end members of silica derivation on the basis of Si isotopic signatures: direct precipitation of silica from seawater on the seafloor, alteration of a precursor rock (volcanic, carbonate, siliciclastic) by addition of silica from seawater, and silica precipitation from hydrothermal vents. Only in the first case does the chemical and isotopic composition of chert reflect the chemistry and temperature of Archean seawater.

Chert is very resistant to surface weathering and associated chemical alteration. Therefore, chert is often considered to be the ideal agent for the preservation of very ancient and potentially extraterrestrial biosignatures (Westall 2008).

Overview

Cherts, both sedimentary (authigenic) and as a secondary alteration product, form by precipitation from aqueous fluids. The solubility of silica (Dove and Rimstidt 1994; Fleming and Crerar 1982) in water is largely independent of its pH for pH lower than 9 but increases exponentially for pH >9. Solubility of silica also increases with increasing temperature and with increasing salinity. During the Archean, precipitation of silica was most likely abiogenic and either derived originally from ocean-floor hydrothermal vents or from regional precipitation from normal but silica-supersaturated seawater. From ~1.8 Ga ago (Maliva et al. 2005), the silica cycle in the oceans began to be governed, as it still is, by silica-secreting organisms. Radiolaria are thought to have appeared in the late Cambrian diatoms in the Jurassic. Since then, most silica derived from continental weathering and delivered by rivers to the oceans is biologically consumed (Laruelle et al. 2009).

For our understanding of the evolution and conditions of early life, the chert units found in early and mid-Archean stratigraphic sequences such as in the Pilbara Craton (Australia) and Barberton Greenstone Belt (South Africa) are most important. Both sequences, the Warrawoona Group in the Pilbara Craton and the Onverwacht Group in the Barberton Greenstone Belt, consist predominantly of mafic to ultramafic volcanic units, with minor felsic volcanic and associated volcanoclastic units (3.47–3.3 Ga). Both sequences are so similar that they may have been part of a single terrain at the time of deposition (Zegers et al. 1998). Chert units (typically less than 20 m thick) cap volcanic sequences and can commonly be traced over large (>50 km) distances (Kato and Nakamura 2003). A few thicker chert units occur in both the Pilbara Craton and Barberton Greenstone Belt: the Strelley Pool Chert and the Buck Reef Chert (350 m, Hofmann and Harris 2008), respectively. The detailed study of the Strelley Pool Chert (~3.43 Ga) by Allwood et al. (2006) showed that the chert consists of at least four members with different characteristics and compositions, some of which show excellently preserved ► [stromatolites](#). The unit

was most likely deposited as a dolomite/carbonate reef on a shallow platform consisting of felsic volcanoclastic sediments. Tice and Lowe (2004) studied in detail the Buck Reef Chert, and sedimentary structures were interpreted to represent deposition in a shallow- to deep-marine environment, with organic matter in the shallow-water facies resulting from photosynthetic microbial mats.

Other chert units in the earliest greenstone sequences show no strong evidence of carbonaceous and clastic sedimentary deposition but are more likely to represent deposition of silica directly from oversaturated seawater. Silica is thought to have been released from nearby ocean-floor hydrothermal vents even though these can only rarely be documented. These cherts show no macroscopic biogenic textures, but have been studied extensively for microtextures that might be indicative of fossilized microorganisms and microbial mats (Schopf et al. 2002; Westall et al. 2006; Westall 2008; Sugitani et al. 2013). Some of the most famous putative microtextures were found in the ► [Apex Chert](#) (Schopf et al. 2002). The claim that those filamentous textures represented evidence for life at 3.45 Ga was countered by studies showing that similar textures could be generated in hydrothermal systems by Fischer-Tropsch-type abiotic processes (Brasier et al. 2002).

Because chert is so resistant to erosion, it provides a good record for any study of ► [early Earth conditions](#). Samples from the Marble Bar Chert (► [Pilbara](#), Australia) have been used for paleomagnetic studies (Suganuma et al. 2006). Oxygen and Si isotopic compositions in chert have been used to infer the temperature of the Archean ocean (Knauth and Lowe 2003; Robert and Chaussidon 2006) of up to 70 °C. However, van den Boorn et al. (2010) showed that the samples used in those studies were most likely deposited from hot hydrothermal water rather than from ambient seawater. They suggest a maximum temperature of ambient seawater of 55 °C.

Because of its formation by precipitation from water and the potential to preserve textural and geochemical proxies for fossil life, chert is one of the targets to detect former life

on Mars (Westall 2008). The ► [Mars Exploration Rover Spirit](#) recently found amorphous silica (a precursor to chert) in the Gusev Crater (Rice et al. 2010).

Key Research Findings

Chert units in Archean greenstone belts represent the oldest sedimentary units in otherwise entirely volcanic sequences. Stratiform chert units may be the result of direct precipitation from oversaturated seawater or may represent hydrothermal deposits. In some cases, units that originally contain largely carbonate (dolomite, siderite) have been pervasively silicified. Some of those units contain stromatolites and other micromorphological indications of biological activity.

Applications

Chert is very resistant to weathering and chemical alteration under surface conditions. This makes chert units, if they can be shown to have formed in the Archean, ideal recorders of Archean conditions, to be probed by a variety of techniques.

Future Directions

Chert units will continue to be studied as some of the best recorders of the conditions of early life. To correctly interpret micromorphological and geochemical signatures, the context of chert units and their surroundings must be considered closely. To obtain a continuous stratigraphic sequence, unaltered by surface conditions and unaffected by lightning strikes (for paleomagnetic studies), it will be important to drill cores through chert units. Such core samples should be studied collaboratively using different techniques and methods to obtain a more accurate insight into the conditions of life in the Archean. Amorphous silica deposits on Mars deserve full attention in preparation for future missions such as ExoMars and Mars Sample Return.

Chicken or Egg Problem

Henderson James CleavesII
 Earth-Life Science Institute (ELSI), Tokyo

 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

Chicken or egg problems are apparent causality problems; for example, which came first, the chicken or the egg? This is paradoxical because chickens are required to lay eggs, and yet chickens hatch from eggs. An apparent paradox in modern biochemistry is the fact that nucleic acids (both DNA and RNA) are required to make coded proteins, and at the same time, coded proteins are required to make nucleic acids. In the origin and early evolution of life then, it is not apparent which of these two must have come first. One possible solution to this problem is offered by the discovery of ribozymes, RNA molecules which could potentially code for their own replication and serve as catalysts for their replication as well.

Chicxulub Crater

Philippe Claeys
 Analytical-Environmental & Geo-Chemistry,
 Vrije Universiteit Brussel, Brussels, Belgium

Keywords

Carbonaceous chondrites · Dinosaurs · Crater (impact) · Mass extinctions · Meteorites

Definition

The Chicxulub structure is a large impact crater formed 66 Ma ago at the tip of the Yucatan Peninsula (Mexico). With a diameter between 180 and 220 km, it is the second largest impact crater known on Earth after Vredefort (South Africa) and the only one with a well-preserved peak-ring. The Chicxulub impact is considered the cause of the last major mass extinction, at the Cretaceous-Paleogene (KPg) boundary (or previously ► [KT boundary](#)). This mass extinction led to the disappearance of 75% of the fauna and flora on the continent and in the oceans, including emblematic organisms such as ammonites and all the nonavian dinosaurs.

Overview

The Chicxulub structure formed by the collision of a projectile, most likely a ~10–12 km in size ► [carbonaceous chondrite](#) meteorite (Goderis et al. 2013), with the Earth crust. In the end Cretaceous, the Yucatan region consisted of a shallow to deep water carbonate and evaporite platform overlying a gneiss-granitic basement. Buried under ~1 km of Cenozoic sediments, geophysical methods were used to image the morphology and characteristics of the structure. Seismic data showed the cavity concave morphology, its multi-ring structure as well as the excellent preservation

of its central peak-ring (Morgan and Warner 1999), in analogy with large craters observed on other planets (Moon, Mars...). Gravity measurements also clearly outlined the central-peak ring surrounded by a region of lower density forming the trough zone. A magnetic anomaly, likely caused by the presence of iron-rich rocks, corresponds to the uplifted central peak area. The crater was drilled first for oil exploration purposes (unsuccessful) in the 1970s, and again onshore in 2002 by the International Continental Scientific Drilling Program (ICDP, see Urrutia-Fucugauchi et al. 2004 for a summary), revealing the stratigraphy and proportion of carbonate and evaporite within the target rock and sampling the impactites. Based on ^{40}Ar – ^{39}Ar dating of the latter, the crater formed exactly 66 million years ago (Swisher et al. 1992; Renne et al. 2013), which stratigraphically correspond to the KPg boundary.

In 2016, Expedition 364 of the International Ocean Discovery Program (IODP) together with the ICDP drilled the offshore part of the peak-ring structure down to ~1335 m. The recovered cores contain below Cenozoic sediments: a KPg transition zone, ► [suevite](#) of various grain sizes, different types of impact melt rocks, as well as fractured, sheared, and shocked uplifted granitic basement, cut by numerous dikes, characterized by low density and low seismic velocity. These characteristics and the omnipresence of shock metamorphism (~25 GPa) within the granite support the dynamic collapse model of peak-ring formation process (Morgan et al. 2016); a key element to better understand cratering on rocky planets. The transition zone from impactite to Paleogene sediments shows that life reappeared in the crater shortly (30 kyr) after the impact (Lowry et al. 2018), implying that proximity to Chicxulub did not affect recovery. The famous worldwide Ir positive anomaly occurs at the top of this transition sequence confirming without a doubt the link between the crater formation and the KPg boundary (Goderis et al. 2021). Gulick et al. (2019) provide an account of the processes that occurred within a time frame of minutes to days directly after the impact: from peak ring formation and collapse, followed by rapid ocean resurge within the cavity, to the arrival of tsunami

and the complex deposition of reworked sediments and suevite. The crater impactites are described by Feignon et al. (2021), De Graaff et al. (2022), and Kaskes et al. (2022). Geochemically, these impactites are clearly connected to the proximal ► [ejecta](#) material spread all over the Gulf of Mexico, while the more distal ejecta, transported through the atmosphere, covers the entire planet (Schulte et al. 2010).

The release and injection at high altitudes (25 km) in the atmosphere of climate active gases (CO_2 ; SO_x , H_2Ov), released by shock vaporization of the carbonate and evaporite from the target rock, and fine dust are responsible for the global consequences of the impact at Chicxulub. Using 3D hydrodynamic code SOVA and taking into consideration the following: impact angle (45° to 60° according to Collins et al. 2020), sediment properties, average shock pressure, and water depth, Artemieva et al. (2017) estimate that 325 ± 130 Gt of sulfur and 425 ± 160 Gt CO_2 were ejected, more than enough to induce severe changes to the global climate. Together with the pulverized fine dust, these gases likely led to yearlong darkness and brutal cooling all over the Earth, strongly reducing photosynthesis and triggering the biosphere collapse. Using a lower volume of gases produced, Brugger et al. (2017) estimate that sulfate aerosols caused a 25°C cooling of the average temperature, lasting between 10 and 30 years after the collision. In the ocean, carbonate productivity (mainly CaCO_3 plankton) significantly decreased, perhaps related to a brutal postimpact drop in pH of the surface-ocean, supporting ocean acidification as a key mechanism for the ecological collapse in the marine realm, followed by major perturbation of global carbon cycle (Henahan et al. 2019).

Definition

The term chirality, from the Greek word *cheir* for “hand,” refers to the property of “handedness” possessed by some molecules and macroscopic objects. A molecule or object is chiral if it is not superimposable on its mirror image, as is the case for left and right hands. The word was introduced by Lord Kelvin (1904) and has been further quantified by Mislow (1965) and Cahn et al. (1966), who define an object as chiral when it contains no element of symmetry (excepting in some cases an axis of rotation). The two distinct mirror-image forms are called enantiomers in the case of chiral molecules and enantiomorphs in the case of chiral crystals.

Overview

The two enantiomers of a chiral molecule have identical physical and chemical properties, which was demonstrated by van't Hoff and Le Bel using arguments about the “exact mechanical symmetry” between enantiomers (van't Hoff 1887). It has since been proven, however, that because of parity violation, there is a minute – and, to date, experimentally immeasurable – energy difference between enantiomeric molecules, which by current predictions lie in the range of femto- to picojoules/mol (Quack 2002).

Each of the two enantiomeric forms of a molecule interacts differently with other chiral molecules, chiral objects, or chiral forces such as plane-polarized light. Such chiral interactions form the basis for the molecular recognition that enables the specificity of reactions observed in biological systems.

A collection of enantiomers of a molecule may be comprised of equal amounts of each hand (a racemic mixture), all of a single hand (an enantiopure mixture), or any fraction of each enantiomer (a scalemic mixture). The standard definition of enantiomeric purity, known as the enantiomeric excess, arose from the observation that pure enantiomers rotate the plane of polarized light to the same degree but in opposite directions. Thus, an equal mixture of left- and right-handed molecules exhibits no rotation of plane-polarized light. The enantiomeric excess of a collection of enantiomeric molecules is defined by the degree and direction of rotation compared to the enantiopure case and is given by Eq. 1:

$$\% \text{enantiomeric excess} = \%ee = 100 \cdot \frac{R - S}{R + S}$$

where R and S are defined in the following paragraph.

The term homochirality typically refers to the fact that the two main building blocks of biological molecules, sugars and amino acids, each exist in only one of the two possible enantiomeric forms. Convention describes these as right-handed, R , or d-sugars and left-handed, S , or l-amino acids. The term homochirality was introduced by Lord

Kelvin, who wrote: “two equal and similar right hands are homochirally similar” (Lord Kelvin 1904). This description could apply, for example, to a series of different amino acids with all in the same enantiopure form or to an enantiopure collection of molecules of a single amino acid. Biopolymers formed from d-sugars, such as RNA and DNA, and from l-amino acids, such as polypeptides and proteins, are homochiral.

In the modern literature concerning origin of life, the term homochirality has become synonymous with the single-handedness of the molecular building blocks and biopolymers of living systems. Homochirality has been suggested as a possible biosignature, an idea that has been expressed even more strongly as “the homochiral imperative of molecular evolution” (Siegel 1998) or by the tenet of “No homochirality, no life!” (Bonner 1998). More recent experiments demonstrating that a d-polymerase ribozyme could evolve to catalyze the cross-chiral replication of its mirror image suggest the possibility that replicating d- and l-RNA molecules may have emerged together (Szczepanski and Joyce 2014). In such a scenario, the homochiral path of modern life might have arisen from later evolutionary pressures on early forms of life.

Emergence of Homochirality

The abiotic synthesis of chiral molecules results in a racemic mixture of products in the absence of a chiral bias that helps to direct the reaction preferentially toward one hand. In modern organic synthesis, such a chiral bias may be obtained from the pool of enantioenriched molecules produced by living systems. In a prebiotic world, however, prior to the presence of a chiral pool, racemic mixtures of chiral molecules would be expected from such reactions. How a racemic prebiotic world came to develop life based on single chirality is a central problem that has intrigued scientists for generations. It is in fact two questions (Blackmond 2009): First, how was an initial chiral bias induced, known as symmetry breaking? And second, how was such an imbalance sustained and propagated to high levels of enantiopurity?

Proposals for how an imbalance initially came about may be classified as either terrestrial or

extraterrestrial and then subdivided into either random or deterministic, sometimes called “*de facto*” and “*de lege*,” respectively (Quack 2002). Evidence of small enantiomeric excesses in amino acids found in chondritic meteor deposits has been suggested to support the extraterrestrial breaking of symmetry (Burton et al. 2012). The possible role of parity violation energy differences fits into a “*de lege*” model, although to date no chemical or physical difference between enantiomers has been confirmed in experiments.

Proponents on the “chance” side of this question suggest that symmetry breaking could occur stochastically due to transient fluctuations in the physical and chemical environment. However, any small imbalance created in this way should average out as the racemic state unless some process intervenes to sustain and amplify it. Thus whether or not the imbalance in enantiomers came about by chance, arising on Earth or elsewhere, an amplification mechanism remains the key to increasing enantiomeric excess.

Theoretical work from the 1950s (Frank 1953) and experimental studies from the 1990s to the present day have provided a number of proposals for the amplification of a small initial imbalance in enantiomers. Experimental models invoke both chemical reactions and physical phase behavior to rationalize enantioenrichment. Chemical models invoke autocatalytic reactions, chirality transfer, or kinetic resolutions, while physical models exploit aspects of the crystallization behavior of chiral molecules to provide enantioenrichment of either the solid or solution phases.

Chemical Models for Enantioenrichment

The Soai reaction provides the most robust experimental example of asymmetric autocatalytic amplification of enantiomeric excess (Soai et al. 1995). Although the chemistry is not itself prebiotically plausible, the reaction provides the first experimental proof of concept of the Frank model for the emergence of homochirality (Blackmond 2004). Catalysis of the formose reaction by amino acids (Breslow and Cheng 2010) or amino acid salts (Hein and Blackmond 2012) leads to enantioenrichment of the resulting

glyceraldehyde, the smallest chiral sugar. The transfer of chirality to amino acids via transamination reactions has been demonstrated (Levine et al. 2008). A kinetic resolution of sugars by amino acids – or, conversely, of amino acids by sugars – results in significant enantioenrichment (Hein et al. 2011) of precursors in a prebiotically plausible route to RNA (Powner et al. 2009).

Physical Models for Enantioenrichment

Ever since Pasteur used tweezers to separate the mirror-image crystals of the di-salt of tartaric acid, crystallization processes and the phase behavior of chiral molecules have intrigued scientists as a potential means for the emergence of homochirality. Kondepudi showed striking amplification of the enantiomeric excess of NaClO_3 crystals by rapidly stirring supersaturated solutions (Kondepudi 1990), and Viedma showed that racemic mixtures of these same crystals evolved to homochirality under the influence of attrition (Viedma 2005). The former case is noted as a “far from equilibrium” process, while the latter takes place close to equilibrium; both rely on the fact that while NaClO_3 is achiral in solution, it forms separate left- and right-handed crystals. It was recognized that such processes for chiral amplification might be extended to intrinsically chiral molecules that form separate crystals (called conglomerates) if the enantiomers could be made to exchange rapidly in solution. The first proof of concept of attrition-enhanced deracemization of intrinsically chiral molecules was demonstrated for amino acid derivatives (Noorduyn et al. 2008) and for a proteinogenic amino acid (proteinogenic refers to amino acids that are precursors to proteins) (Viedma et al. 2008).

The majority of chiral molecules – including 17 of the 19 proteinogenic amino acids that are chiral – do not crystallize as conglomerates or separate left- and right-handed crystals, but instead form heterochiral crystals usually comprised of a 1:1 ratio of enantiomers, called racemic compounds. Models for enantioenrichment based on the phase behavior of racemic compounds rely on the thermodynamic partitioning of the enantiomers between the solution and solid phases.

A system containing an unequal number of left- and right-handed molecules in an equilibrium mixture of crystals in saturated solution contains both the heterochiral solid and an enantiopure solid of the enantiomer present in excess. The composition of the solution phase – that is, the solution enantiomeric excess – is a constant value dictated by the Gibbs phase rule. Known as the eutectic composition, this is a characteristic property of each amino acid and is related to the relative solubilities of the heterochiral and homochiral solids. For example, serine and valine exhibit eutectic compositions of 99% ee and 47% ee, respectively. This property was first recognized as a possible route to enantioenrichment by Morowitz (1969) and was elaborated by Blackmond and coworkers (Klussmann et al. 2006a, b) and by Breslow and coworkers (Breslow and Cheng 2009). A similar approach to enantioenrichment via sublimation of amino acids has been reported (Fletcher et al. 2007; Perry et al. 2007).

The explosion of experimental reports on the subject of the emergence of biological homochirality in the first decade of the twenty-first century led *Chemistry World* to suggest that we are now “spoilt for choice” (Ball 2007) in proposals for answering the puzzle of the single chirality of life on Earth.

Chiron

Therese Encrenaz
LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Definition

Chiron, discovered in 1977, was first identified as an ► [asteroid](#), labeled 2060 Chiron. In 1989, as the object was moving toward perihelion, a coma was discovered and it was also designated as a comet, 95 P/Chiron. Chiron is the first identified object among the class of the ► [Centaurs](#) which orbit between Jupiter and Neptune. Its period is 50 years and its perihelion distance is 8.4 AU. Its diameter is about 180 km and its albedo is about 0.05. Chiron is now considered to belong to the C-type class of asteroids. Like other Centaurs, Chiron is assumed to be originally a ► [trans-Neptunian object](#) which escaped from the ► [Kuiper Belt](#).

Chloromethane (CH₃Cl)

Audrey Coutens
Laboratoire d'Astrophysique de Bordeaux,
Pessac, France

Synonyms

CH₃Cl; Freon-40; Methyl chloride; R40

Chemical Formula

CH₃Cl

Definition

Chloromethane is a colorless and poisonous gas. It is the most abundant of the organohalogens present in the Earth's atmosphere and is produced by both natural and synthetic pathways. Chloromethane was formerly used as a refrigerant. This use was, however, discontinued because of its toxicity and flammability. Chloromethane was identified in our ► [Solar System](#), both on Mars (Glavin et al. 2013) and in the coma of the comet ► [67P/Churyumov–Gerasimenko](#) (Fayolle et al. 2017). It was also detected in the ► [interstellar medium](#) towards the two components of the protostellar binary ► [IRAS 16293–2422](#) (Fayolle et al. 2017).

History

Chloromethane was detected for the first time in the ► [interstellar medium](#) in 2017 (Fayolle et al. 2017).

Chloroplast

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Chloroplast is a ► [chlorophyll](#)-containing organelle of phototrophic eukaryotes responsible for the generation of energy from radiation. A major feature of eukaryotic cells, absent from prokaryotic cells, is the presence of membrane-enclosed structures called ► [organelles](#). These include mitochondria and chloroplasts, the latter only in photosynthetic cells. Like mitochondria, chloroplasts have a permeable outermost membrane, a much less permeable inner membrane, and an intermembrane space. The inner membrane surrounds the lumen of the chloroplast, called stroma. Chlorophyll and all other components needed for ► [photosynthesis](#) are located in a series of flattened membrane disks called thylakoids. The thylakoid membrane is highly impermeable to ions and other metabolites because its function is to establish the ► [proton motive force](#) necessary for ATP synthesis. In green ► [algae](#) and plants, thylakoids are typically stacked into discrete structural units called grana. The chloroplast stroma contains large amounts of the enzyme ribulose biphosphate carboxylase (RubisCO). RubisCO is a key catalyst of the Calvin cycle, the series of biosynthetic reactions by which most photosynthetic organisms convert CO₂ to organic compounds. RubisCO makes up over 50% of the total chloroplast protein and catalyzes the formation of phosphoglyceric acid, a key compound in the biosynthesis of glucose. The permeability of the outermost chloroplast membrane allows glucose and ATP produced during photosynthesis to diffuse into the cytoplasm where they can be used to build new cell material. On the basis of their relative autonomy, size, and morphological resemblance to prokaryotes, it was

suggested that chloroplasts were descendants of bacteria by ► [endosymbiosis](#). There is different structural, functional, and molecular evidence that supports the endosymbiotic origin of chloroplasts: existence of a small genome, presence of ribosomes, antibiotic specificity, and molecular phylogeny.

Chondrite

Frank Sohl

DLR, Institute of Planetary Research, Berlin,
Germany

Definition

Chondrites are undifferentiated stony ► [meteorites](#) and represent the majority among stony meteorites. The term literally means “with ► [chondrules](#)” and therefore underlines the main difference to ► [achondrites](#). Chondrites consist of a fine-grained matrix of micrometer-sized dust particles, surrounding roughly millimeter-sized, round inclusions (► [chondrules](#)), refractory ► [CAIs](#) (*Ca-Al-rich inclusions*), particles enriched in metallic Fe-Ni and sulfides, and

other individual mineral grains. The matrix also contains presolar grains that formed elsewhere in the Galaxy before the Solar System came into being. The presence of ► [chondrules](#) indicates that chondrites were formed by accretion of thermally processed dust particles, whereas their primitive parent bodies never experienced partial melting and recrystallization. The class of chondrites has been divided into enstatite (EH and EL types), Rumuruti (R type), ordinary (H, L, and LL types), and ► [carbonaceous](#) (C types); the latter is subject to aqueous alteration and thought to be the most primitive meteorites. H, L, and LL indicate high-iron, low-iron, and low-iron/-metal contents, respectively.

Chromatographic Coelution

Jason P. Dworkin

Astrochemistry Laboratory, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Synonyms

[Co-elution](#)

Definition

Chromatographic coelution occurs when two (or more) compounds do not chromatographically separate due to the fact that both species have retention times that differ by less than the resolution of the method. This can be solved by increasing the selectivity and/or efficiency of the ► [chromatography](#) or by employing different detection techniques that can differentiate the coeluting compounds. Changing the chemistry of the mobile phase, stationary phase, temperature, and column or plane length are good methods to increase the separation. Techniques such as mass spectrometry and optical spectroscopy are common ways to distinguish between coeluting compounds that cannot be resolved (Fig. 1).

Chromatographic Coelution, Fig. 1 Chromatographic co-elution can be resolved by adjusting the chromatographic conditions. In these reverse phase HPLC traces, fluorescently labeled amino acids are resolved by decreasing the methanol concentration in the mobile phase from trace A to trace B

Chromatography

Jason P. Dworkin
Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Keywords

Column chromatography · GC · Hyphenated techniques · LC · Planar chromatography · Separation science · Solid phase extraction

Definition

Chromatography (either preparative or analytical) is a qualitative or quantitative experimental method based on the properties of all molecules to partition more or less selectively from one phase into another and therefore to migrate at different rates when they are carried across a solid or liquid stationary phase by a mobile phase, which can be a gas, liquid, or supercritical fluid.

Overview

Chromatography is a broad laboratory method for physically separating compounds from a mixture based on the preferential partitioning of different molecules across two different phases. The analyte is carried in the mobile phase (gas, liquid, or supercritical fluid) and then passes through a stationary phase (liquid or solid), and some analytes are retained more efficiently than others. Different types of chromatography are based on the geometry (through a stationary phase-filled tube or “column” or over a plate or “plane” with stationary phase), the type of mobile/stationary phase interaction (gas/liquid, gas/solid, liquid/liquid, liquid/solid, supercritical fluid/solid), and the nature of the analyte/stationary phase interaction (e.g., host/guest chemistry, hydrophobic interactions, ion exchange, hydrodynamic volume, volatility, etc.). ► [Electrophoresis](#), while not strictly chromatography, is closely related.

While planar chromatography (e.g., paper and thin layer (TLC)) is typically qualitative, column chromatography is well suited for real-time interrogation of the eluting compounds with detectors. Common types of gas-liquid chromatography (GC) detection techniques are flame ionization detection, thermal conductivity, and any number of mass spectrometric techniques (GC-MS). Common detectors in liquid/solid chromatography (LC or ► [HPLC](#)) are ultraviolet absorbance, fluorescence, refractive index, and various mass spectrometric methods (LC-MS). The addition of more elaborate detectors with a chromatographic or capillary

electrophoretic “front end” (or “inlet”) is collectively referred to as hyphenated or hybrid techniques. Combinations of chromatography with ► [mass spectrometry](#), nuclear magnetic resonance, and optical spectroscopy increase the ability of an analytical chemist to study small quantities of complex mixtures.

Conversely, preparative chromatography (either column or planar) is used to purify large quantities of a compound of interest. While GC or supercritical fluid chromatography is sometimes used, the most popular method is LC (or electrophoresis). One popular method is solid-phase extraction (SPE).

While the majority of chromatography is conducted in laboratories or industry, the process can be found elsewhere. Naturally occurring chromatography is typically fractional distillation or geochromatography, where, for example, compounds dissolved in water are roughly separated as they pass through rocks or sediment columns. Chromatography (GC-MS) has also been used in robotic planetary science missions to study Mars; Saturn’s moon, Titan; and comets.

[Isotopes of chromium](#)

Chemical Formula

^{50}Cr , ^{52}Cr , ^{53}Cr , and ^{54}Cr

Definition

The transition metal chromium (Cr) has four naturally occurring stable isotopes; ^{50}Cr (4.345%), ^{52}Cr (83.789%), ^{53}Cr (9.501%), and ^{54}Cr (2.365%) as well as 22 synthetic radioactive isotopes with ^{51}Cr being the most stable with a half-life of 27.7 days. Cr has an atomic number of 24, and a standard atomic weight of 51.9961. The stable isotopic composition of Cr is generally reported in delta notation as $\delta^{53}\text{Cr}_{(\text{NIST-979})} = [({}^{53}\text{Cr}/{}^{52}\text{Cr})_{\text{substance}} / ({}^{53}\text{Cr}/{}^{52}\text{Cr})_{\text{NIST-979}} - 1]$, where substance is a material of interest and NIST 979 is a certified Cr nitrate solution with the relative isotope abundances noted above.

History

Measurements of Cr stable isotope ratios were initially applied in astrophysics to study the origins of the Solar System (Birck and Allègre 1984,

1988). The relatively short-lived radionuclide ^{53}Mn decays to ^{53}Cr in 3.7 Ma. Variability in the relative abundance of ^{53}Cr , as measured, for example, through the ratio of ^{53}Cr to ^{52}Cr thus provides information on the abundance of the now extinct ^{53}Mn isotope during the formation of Solar System objects like meteorites (Birck and Allègre 1984, 1988). Combined with the decay rate of ^{53}Mn , Cr isotope ratios in Solar System objects provide information on their timing of formation and inform models of nucleosynthesis (Birck and Allègre 1984, 1988). Stable Cr isotope ratio measurements were subsequently adopted to track natural attenuation of hexavalent Cr (Cr(VI)) in Cr contaminated groundwater (Ellis et al. 2002). The utility of stable Cr isotope measurements in tracking Cr(VI) attenuation arises from the stable isotope fractionation that accompanies the reduction of Cr(VI) to trivalent Cr (Cr(III)), which is much less soluble and more particle reactive than Cr(VI) (Ellis et al. 2002). As Cr(VI) is progressively reduced to Cr(III), the isotopic composition of residual Cr(VI) becomes heavier (i.e., $\delta^{53}\text{Cr}_{(\text{NIST-979})}$), and thus isotope ratio measurements inform on the extent of Cr (VI) reduction (Ellis et al. 2002). Following application of Cr stable isotope ratio measurements to Cr (VI) natural attenuation, studies found that equilibrium fractionation was only expected during redox reactions of Cr (Schauble et al. 2004) and that the Cr stable isotope composition of igneous rocks all fell within a very narrow range (Schoenberg et al. 2008) ($\delta^{53}\text{Cr}_{(\text{NIST-979})} = -0.124 \pm 0.101\%$ (2 SD)). Application of Cr isotopes to reconstructing the evolution of Earth surface chemistry began with the finding that Cr isotope ratios in marine chemical sediments appeared to broadly track the oxygenation of the atmosphere between the Archean and Phanerozoic Eons (Frei et al. 2009). This finding prompted numerous studies that applied Cr isotope ratio measurements in geological materials as a paleo-oxygen proxy (Cole et al. 2016; Crowe et al. 2013). At the same time, efforts to determine the multiple physical-chemical-biological processes that redistribute Cr and fractionate its isotopes in relevant Cr reservoirs intensified (Basu and Johnson 2012; Berna et al. 2010; Døssing et al. 2011).

Overview

Cr stable isotope ratio measurements are used in astrophysics, environmental chemistry, oceanography, and geobiology. Cr stable isotope ratio measurements are commonly conducted using either Thermal Ionization Mass Spectrometry (TIMS) or Multicollector-Inductively Coupled Plasma-Mass Spectrometry (MC-ICP-MS) following Cr purification through ion exchange resins (Qin and Wang 2017). Application of Cr stable isotopes in astrophysics is generally restricted to analyses of meteorites to determine variability in ^{53}Cr abundance as a proxy for now extinct ^{53}Mn (Birck and Allègre 1984, 1988). Cr stable isotope variability in meteorites is small and thus very high precision isotope ratio measurements are required (Birck and Allègre 1984, 1988). Measurements of Cr isotope ratios in terrestrial igneous rocks also show limited variability ($\delta^{53}\text{Cr}_{(\text{NIST-979})} = -0.124 \pm 0.101\%$ (2 SD)) (Schoenberg et al. 2008). Larger Cr isotope fractionations (are known to accompany the reduction of Cr(VI) to Cr(III) at Earth's surface and this can give rise to large ($>1\%$) differences in the $\delta^{53}\text{Cr}_{(\text{NIST-979})}$ of redox cycled Earth surface materials. Cr(VI) is known to form on the Earth's surface due to reactions with strong oxidants like manganese oxides (Fendorf and Zasoski 1992), or hydrogen peroxide (Pettine and Millero 1990). The presence of Cr(VI) in Earth's surface environments is thus thought to require an atmosphere-ocean system oxygenated through biological photosynthesis (Frei et al. 2009; Crowe et al. 2013), though traces of strong oxidants can be generated through abiotic photochemical reactions (Availability of O_2 and H_2O_2 on Pre-Photosynthetic Earth 2011). It is also worth noting that Cr(VI) itself is a strong oxidant and a carcinogen (Norseth 1981)—Cr(VI) can accumulate to naturally high concentrations due to oxidative weathering of ultramafic rocks (Oze et al. 2007), and in cases, it has been released into the environment due to anthropogenic activities. Reduction of Cr(VI) is accompanied by a strong kinetic isotope fractionation effect, which can vary in magnitude depending on the specific reductant, and invariably leads to enrichment of

the light isotopes in the Cr(III) product (Ellis et al. 2002; Døssing et al. 2011; Kitchen et al. 2012; Basu et al. 2014). Groundwater models that apply known fractionation factors can thus be used to predict the extent of Cr(VI) reduction based on the isotopic composition of residual Cr(VI) (Berna et al. 2010). In contrast, experiments to date imply limited fractionation associated with oxidation of Cr(III) to Cr(VI) (Zink et al. 2010). Experiments, however, show that Cr(III) chelation by strong organic ligands can induce appreciable fractionation (Saad et al. 2017). Theory predicts that equilibrium fractionation between Cr(VI) and Cr(III) species leads to enrichment of the light isotopes in Cr(III) and also predicts negligible equilibrium isotope fractionation between inorganic Cr(III) species (Schauble et al. 2004). The extent to which equilibrium fractionations between Cr species are expressed in the environment depends on the kinetics through which isotope exchange between species occurs. Collectively, existing experimental and theoretical data imply strong kinetic Cr isotope fractionation associated, with Cr(VI) reduction to Cr(III) and Cr(III) chelation with relatively modest fractionations associated with other Cr reactions.

Cr exists in Earth's continental crust primarily as Cr(III) hosted in minerals like chromite (Cr_2O_3) and in silicates like amphiboles and pyroxenes. The stable isotopic composition of most crustal rocks is similar to igneous rocks and mantle derived rocks are also comparable (Schoenberg et al. 2008). Weathering of the crust primarily delivers these minerals as detritus to the oceans, but also leads to the limited dissolution of Cr and its delivery to seawater as dissolved Cr(III), or Cr(VI), if oxidized as described above (D'Arcy et al. 2016; Wu et al. 2017). Weathering is accompanied by Cr isotope fractionation and Cr(VI) in rivers is isotopically heavy relative to igneous rocks. Cr accumulates in seawater (concentrations), where it variably exists as Cr(III) and Cr(VI) (Pettine and Millero 1990). The isotopic composition of Cr in seawater is also variable and exhibits an inverse, log-linear, relationship with Cr concentration (Scheiderich et al. 2015). This log-linear relationship, colloquially referred to as the global-Cr-array, implies a

defined isotope fractionation factor ($0.08 \pm 0.03\%$ (2 SD)) associated with the removal of Cr from seawater. Marine sediments contain Cr mostly as detrital minerals, which thus have isotopic compositions similar to or identical to the continental crust (Schoenberg et al. 2008; Gueguen et al. 2016). Authigenic Cr, derived from seawater, can be enriched in chemical sediments (e.g., carbonates (Bonnand et al. 2013), or iron oxides) or siliciclastic sediments deposited under anoxic conditions (Gueguen et al. 2016). Authigenic Cr can have Cr isotope ratios offset from seawater due to fractionation associated with Cr removal to the sediment (Gueguen et al. 2016). When fractionation associated with Cr removal is known, analyses of Cr isotopes in authigenic Cr preserved in sediments and sedimentary rocks can be used to reconstruct the isotope composition of seawater, which itself is set by a combination of the isotope fractionation associated with removal and that associated with weathering and runoff. Given that large fractionations are only known to occur as the result of Cr(VI) reduction and Cr(III) chelation, the sedimentary stable Cr isotope record is most sensitive to Cr redox reactions and possibly the presence of strongly binding Cr(III) ligands in the weathering environment and oceans.

Chromophore

John H. Chalmers

Scripps Institute of Oceanography Geosciences Research Division, University of California, San Diego, La Jolla, CA, USA

Definition

Chromophores are chemical groups that absorb ► **electromagnetic radiation**, for example, in the visible, near-infrared, or ultraviolet ranges, though the original derivation of the word comes from the Greek for color, implying absorption of visible radiation. They may contain systems of conjugated multiple bonds, transition element ions, or both. In biological systems, light absorption by chromophores forms the basis of vision, ► **photosynthesis**, and, in the case of ultraviolet light, ► **mutation** and vitamin D synthesis. In the context of astrobiology, chromophores have been found, for example, in simulated cometary ices. Chromophores are responsible for the colors of dyes, pigments, minerals, and many organisms, though some colors, particularly blues and iridescent effects, are produced by diffraction.

Chromosome

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Definition

Chromosome is a structure consisting of or containing ▶ [DNA](#) with essential genetic information for the cell. In most prokaryotes, it is a circular, double-stranded DNA, normally attached to the cell membrane, with a folded structure (also known as nucleoid) with some attached proteins. In eukaryotic cells, usually the number of chromosomes is characteristic of the species – polyploid plants are a remarkable exception. Somatic cells possess two sets of homologous chromosomes (diploid number or $2n$), one originating from the male progenitor, the other from the female. In contrast, germ-line cells are haploid (n). Eukaryotic chromosomes are located inside the ▶ [nucleus](#) and consist of a double-stranded DNA molecule highly folded and complexed with proteins (histones) also known as chromatin. The term chromosome also applies to the DNA molecules located in mitochondria and plastids and to the genome of DNA viruses.

Keywords

Cratering chronologies · Impact crater · Production function · Radiometric ages · Stratigraphy

Synonyms

[Cratering chronology](#); [Planetary chronostratigraphy](#); [Planetary surface ages](#)

Definition

The term chronology with respect to planetary surfaces generally refers to the timing of events when rock surface units were formed or modified and describes the position of a geologic unit within its stratigraphic context. The term chronology furthermore encompasses the method of deriving ages of planetary surface units by means of radiometric age determinations as well as by analyses of impact crater size-frequency distributions based on knowledge or assumptions of the flux and size distribution of planet-impacting bodies in the history of the Solar System.

Overview

The chronology of planetary surfaces refers to the sequence of geological events that have led to deposition and emplacement of rock-forming units on a planetary surface. The sequence of events and the geologic materials, i.e., the rock-forming units (Wilhelms 1987; Greeley and Batson 1990), are the planet's chronostratigraphic record and have to be seen in a specific planetary context as each planetary body evolves in a different way.

While the chronology in general refers to the timing and sequence of such events, the stratigraphic record of a planet is defined by divisions of geologic time and boundaries of geologic units on a global scale. Divisions of time are characterized by primary or secondary markers considered to be characteristic of that surface. While the geologic time unit (chronologic unit; see Fig. 1) refers to an age derived by various methods as discussed below, a chronostratigraphic unit consists of rocks formed on a global scale during a specific geologic time (Ogg et al. 2008).

The knowledge we have today about the chronostratigraphy and chronology of terrestrial planetary surfaces other than the Earth is based upon the knowledge we have gained during planetary exploration of the ► [Moon](#) (Wilhelms et al. 1971) and was later expanded to other terrestrial surfaces, in particular ► [Mercury](#) and ► [Mars](#) for which formal stratigraphic systems have been developed (Tanaka and Hartmann 2008).

The establishment of timescales for planetary surfaces is based upon geological mapping of planetary surfaces as defined by surface properties, e.g., morphologies, textures, spectral compositions, and, as delineated by geologic contacts, the superposition of individual units following basic stratigraphic principles. Relative ages can be derived by measuring the size-frequency distribution of ► [impact craters](#) that have accumulated in a planet's history through time, which means that densely cratered surfaces are older than less-densely cratered surface units. Thus, a geologic unit records the age as expressed by the number of impact craters formed during meteoritic bombardment and the time a unit was exposed to the projectile impact flux (Öpik 1960; Baldwin 1964; Hartmann 1966; Neukum et al. 1975).

Absolute ages for surface units are constrained by samples returned from the Moon in the course of the lunar Apollo and Luna mission programs. Derived radiometric ages of surface samples have

Chronostratigraphy, Fig. 1 Chronology units in terms of epochs and periods for the terrestrial planets as compiled from different sources; see main text for description; the two columns for Venus' chronology depict the upper and lower estimates for $T = 800$ Ma and $T = 288$ Ma, respectively (1, Ogg et al. (2008), 2, Neukum and Ivanov (1994), 3,

Stöffler and Ryder (2001), 4, Wilhelms (1987), 5, Neukum et al. (2001a), 6, Strom and Neukum (1988), 7, Spudis and Guest (1988), 8, Basilevsky and Head (1998), 9, Basilevsky and Head (2002), 10, Tanaka (1986), 11, Neukum and Wise (1976), 12a, Hartmann and Neukum (2001) Neukum model, and 12b, Hartmann and Neukum (2001) Hartmann model)

established a calibration for the size-frequency distribution of the Moon's surface as observed by remote-sensing imaging. This process allows us to measure model ages for other planetary surfaces either (a) by estimating the relative cratering rates in comparison with the Moon or (b) by directly assessing cratering rates under consideration of impact probabilities and impactor sizes and sources (Neukum and Ivanov 1994; Tanaka and Hartmann 2008) as well as crater scaling laws that describe the relationship between projectile size and impact condition parameters, e.g., velocity, angle, density, and surface parameters, such as surface gravity, density, compositions, and strength of surface materials (Croft 1985; Holsapple 1987; Schmidt and Housen 1987).

For planetary surface chronologies, the number of stratigraphic systems for planetary objects has advanced with new data that have become available in the context of planetary exploration mission. Stratigraphic systems cover the terrestrial (inner) planets as well as the Moon and also the major icy satellites of the Jovian and Saturnian planetary systems.

Basic Methodology

There are different methods of assessing the stratigraphy of planetary surfaces with respect to the relative or absolute age of individual geologic units and their relation to neighboring units. Ages of rocky planetary surface material are determined by means of the decay of radioactive isotopes and decay products if decay rates are known and if samples of surface material are available. In cases where planetary surfaces are observed by remote-sensing methods, ages of surface forming units can only be determined by analyses of impact crater size-frequency measurements, i.e., by comparing the size-frequency distribution of impact craters with the modeled size distribution and impact flux of meteorites on a given planetary surface.

While *relative* age determinations of units allow to assess and estimate the relative sequence of unit-forming events within an area of interest

and in comparison with an established global distribution of impact crater size-frequency observations, age determinations of geologic units based on remotely sensed data with the help of either appropriate scaling laws or modeling of impactor flux allow us to derive *absolute* ages. Except for the Earth, only the Moon has been directly sampled thus far and therefore forms the only natural calibration target for establishing planetary chronostratigraphies and surface chronologies.

Radiogenic Isotope Measurements

Radioactive (or radiometric) dating, i.e., determination of radiogenic isotope ages of rock samples in the context of chronology, makes use of the constancy of rates of radioactive decay by which a radioactive nuclide is transformed to its daughter product. Radiogenic isotope ages for lunar material have been derived using decay measurements of Rb-Sr, Sm-Nd, and $\text{Ar}^{40}\text{-Ar}^{39}$. Such methods are described in detail by, e.g., Dalrymple and Ryder (1991) and Albarède (2009).

For the Moon, over 380 kg of rock material in over 2,000 samples was returned to Earth during the six manned Apollo missions. During the Soviet robotic Luna missions, several hundred grams were collected during three Luna missions and analyzed after return to Earth. Samples are mainly from basaltic rock and impact glass from the lunar mare areas (Apollo 11, 12, 15, 17; Luna 16, 24) as well as from highland terrain (Apollo 14–17, Luna 20). In addition, a number of meteorites found on Earth have a lunar origin (or Martian) and could be radiometrically dated in laboratory measurements; their exact location of origin is, however, unknown.

Lunar rocks on the surface are exposed to cosmic weathering processes and recurrent meteoritic bombardment and therefore are altered. This leads to reprocessing of rocky material and to formation of second- or third-generation rocks (Stöffler et al. 2006). By making use of radioisotope measurements, different ages are usually derived, i.e., (a) crystallization ages, (b) ages of formation of impact breccia, and (c) exposure ages. The crystallization age gives the age of events that led to formation of rock minerals by magmatic or in situ melting processes. Ages for

formation of impact breccia give insight into the age rock material and minerals were transformed to breccias, while the exposure age of rock material gives the age since the rock was exposed to cosmic weathering by cosmic rays (Stöffler et al. 2006). It has, however, been shown that direct radiometric age determinations are only possible for lunar mare basalts, as highland material collected at the lunar surface cannot be related directly to its source area. None of the collected samples were derived from bedrock material due to a several meters thick surface coverage of lunar regolith (e.g., Heiken et al. 1991 and references therein).

Radiogenic isotope measurements for deriving absolute ages of localized samples help to establish boundary age values, but without a careful interpretation of the photogeological settings and the geological context, such measurements cannot contribute to establishing a planet-wide chronology and chronostratigraphic system.

Relative Age Determinations

The easiest accessible approach to assess the time sequence of rock-forming events on a planetary surface is to measure the size-frequency distribution of impact diameters within a geologic unit and to compare this to other geologic units of the same planetary body: the higher the number of impact craters that have accumulated over time per area, the older the surface, which means that a crater frequency measured on a specific geologic unit is representative of the relative age or crater retention age of that unit (Arvidson et al. 1979). A geologic unit or rock-stratigraphic unit is a morphologically distinct entity formed at a specific time by a distinct geologic process (Stöffler et al. 2006). The derived relative surface age does not necessarily reflect the true relative age when a geologic unit was formed, as subsequent processes, generally termed resurfacing, might have led to eliminating impact craters in a given diameter-size range. The main problems arise from accurately identifying and delineating a geologic unit at a given scale, as this significantly depends on the appearance of a particular unit and its relation to surrounding units in the image

data used for photogeologic interpretations (Shoemaker and Hackman 1962; Wilhelms 1987).

By employing cumulative crater size-frequency diagrams, the measured impact crater diameters of all impact craters within a given geologic unit are usually plotted against their cumulative frequency in a log-log diagram. The impact crater size-frequency distribution derived in such a way provides a measure for the surface age with older units, i.e., units with increasing crater retention ages, shifted upwards on the frequency axis (apparent shift toward larger impact crater diameters), while distributions of younger units are shifted downwards on the frequency axis leading to an apparent shift toward smaller impact crater diameter sizes (Hartmann et al. 1981; Wilhelms 1987).

While relative surface age determinations are based upon the interpretation of remotely sensed data by means of determining the superposition of individual rock surface units and by determining impact crater size frequencies, age determinations leading to absolute age values need additional pieces of information.

Absolute Age Determinations

There are two methods of obtaining absolute ages of rock surface units of planetary bodies. One method links radiogenic isotope ages obtained for the Moon with crater retention ages, i.e., relative ages, obtained through photogeological mapping (Hartmann et al. 1981; Neukum 1983; Neukum and Ivanov 1994). In the other approach, models for rates for formation of impact craters are employed and are transferred to other planetary objects considering their specific environment, e.g., position and size, atmosphere, and target properties (Neukum and Wise 1976; Neukum and Hiller 1981; Hartmann et al. 1981; Croft 1985; Holsapple 1987; Schmidt and Housen 1987).

For the ► [terrestrial planets](#) in the Inner Solar System, surface ages can only be obtained by models of the crater forming rates on each one of these bodies. Shapes of crater size-frequency distributions (SFDs) measured on the terrestrial planets, including the Moon, were shown to be

more or less similar which indicates (a) the same family of bodies, preferentially asteroids (Main Belt, Near-Earth asteroids, etc.), impacting these planets, and (b) that time dependences of impact and cratering rates are similar to that for the Moon (Neukum and Hiller 1981; Neukum and Wise 1976; Neukum and Ivanov 1994; Neukum et al. 2001a; Strom et al. 2005).

Lunar-like cratering chronology models were derived for Mercury (Strom and Neukum 1988; Neukum et al. 2001b), ► **Venus** (McKinnon et al. 1997), and Mars (Neukum and Wise 1976; Neukum and Hiller 1981; Hartmann and Neukum 2001). Crater size-frequency measurements were conducted also for a number of asteroids, e.g., 951 Gaspra (Neukum and Ivanov 1994; Chapman et al. 1996), 243 Ida (Neukum and Ivanov 1994), and 253 Mathilde (Chapman et al. 1998).

The impact-cratering chronology model for the Moon is characterized by an exponentially declining impact and crater formation rate in the first 1 Ga following planetary formation 4.55 Ga (e.g., Neukum 1977; Neukum and Ivanov 1994).

Since about 3.8 Ga ago, impact and cratering rates have dropped considerably and reached a more or less constant level at 3–3.3 Ga ago (Wetherill 1975; Neukum 1983; Neukum and Ivanov 1994; Neukum et al. 2001a). Some authors interpreted a peak in radiometric ages of lunar rocks at about 3.9 Ga as an indication for a strong peak in impact and cratering rate (e.g., Tera et al. 1974). They concluded that this so-called Late Heavy Bombardment (LHB) was characterized by a terminal lunar cataclysm rather than by a smooth, exponential decay in impact rate with time. The lunar cataclysm theory has been challenged by dynamic, geologic, and stratigraphic arguments (Wetherill 1975; Neukum and Ivanov 1994; Baldwin 2006).

Absolute ages obtained with an impact chronology model are generally termed cratering model ages, and their units are given in gigayears (Ga = 1 billion years) or megayears (Ma = 1 million years).

Crater size-frequency distributions obtained from crater size-frequency measurements are represented using several techniques, of which

three are commonly adopted. In principle, crater size diameters are grouped into pseudo-logarithmic or logarithmic bins and plotted on the abscissa (Arvidson et al. 1979; Neukum et al. 2001a; Michael and Neukum 2010). The ordinate gives the crater size-frequency values as a function of log diameters. This frequency can either be based upon the cumulative crater diameter sizes (cumulative plots) in which the number of craters with diameters equal or greater than D : $N = N(\geq D)$ is presented or in differential form where the derivative dN/dD of the cumulative size-frequency distribution gives the number of craters in equal diameter bins. The incremental form provides the frequency as a function of the geometric average of fixed-diameter increments (usually $\sqrt{2}$). The relative distribution (R-plot) is the deviation of the size-frequency distribution from a power law: $R = D^3 (dN/dD)$. The choice depends on the details that need to be depicted and highlighted and the analyses that are carried out subsequently.

The size-frequency distribution of an impact crater population can be approximated using either three stepwise power-law segments (Hartmann et al. 2000) obtaining coefficients for the approximation that are characteristic for each SFD. In contrast to the approach by Hartmann, Neukum proposed an analytical polynomial fit (Neukum 1983; Neukum and Ivanov 1994; Ivanov 2001; Neukum et al. 2001a). These functions are termed production functions and are characteristic of each planetary body and derived from numerous observations and measurements of impact craters. Once the production function is fitted, the frequency of impact craters larger than a given diameter (usually N for $D \geq 1$ or N for $D \geq 10$ km) is obtained. This frequency value is subsequently used to derive a surface age from the chronology function obtained earlier which represents the impact-cratering record in the planet's history.

Stratigraphic schemes have been established in principle for all terrestrial bodies. These schemes are based upon stratigraphic marker horizons that are defined by geologic criteria which are different for each object, and they take into account the

superimposed crater size frequencies considered to be a characteristic of a particular unit (Wilhelms 1987). The geologic history of each planet is subdivided into the so-called time-stratigraphic systems. Such chronostratigraphic divisions are termed systems and are further divided into several (e.g., lower, middle, or upper) series. Time-stratigraphic systems and series correspond to periods and epochs as chronologic or chronometric divisions (Wilhelms 1987). The beginning of each period or epoch is defined by the cratering model age derived from the SFD measurement on the unit which defines the base of each system.

Key Research Findings

Stratigraphic sequences have been established in principle for all terrestrial bodies in the Solar System, in particular for the Inner Solar System planets and the Moon. The main stratigraphic sequences and unit-forming events are summarized below, and ages are provided whenever possible. However, age uncertainties are excluded for all model ages, and the reader is referred to references listed in each section. While for several bodies, such as the Moon and Mars, chronostratigraphic systems are well established and applicable, other objects are partly still unknown when it comes to high-resolution data needed for cratering analysis and statistics. Consequently, differences in absolute age dating for each planet between various groups of investigators are due to differences in assumptions of the impact and cratering rates, and many preliminary results are expected to be improved in the course of ongoing planetary missions.

The Moon

The Earth and its Moon are the only bodies in the Solar System for which radiometric ages of rock surface units and soil samples have been obtained. Robotic and manned missions to the Moon have provided the most extensive data set concerning stratigraphy and surface ages available (Wilhelms 1987).

The lunar geologic history is subdivided into periods defined by impact events and impact

crater occurrences ranging from the pre-Nectarian (oldest period), Nectarian, Imbrian, Eratosthenian to the Copernican period (youngest). The Imbrian period is subdivided by the Orientale impact into a late (upper) and early (lower) Imbrian epoch (Wilhelms 1987).

- The pre-Nectarian covers that section of geologic history which predates the Nectarian period, i.e., older than 3.92 (Wilhelms 1987; Stöffler and Ryder 2001) to 4.1 Ga (Neukum and Ivanov 1994). The chronostratigraphic system comprises a number of 30 impact basins, among which is the South Pole-Aitken basin. No traces for volcanic or tectonic processes during the pre-Nectarian period have been found thus far. Traces of pre-Nectarian surface units are mainly found on the lunar farside, and samples returned during the Apollo and Luna missions are later-generation material reworked as breccias in the course of subsequent impact processes (Wilhelms 1987; Stöffler et al. 2006).
- The Nectarian period is defined as the time period between the formation of the Nectaris basin (Janssen Formation) and the Imbrium impact event and comprises at least 11 other large impact-basin forming events. Although some Nectarian-aged volcanic material has been observed (Wilhelms 1987), much of this unit is covered by later impact events that masked Nectarian units. According to recent studies, mare volcanism started already during the Nectarian period with ages of 3.92 Ga and continuing up to 1.2 Ga (Hiesinger et al. 2003). The chronostratigraphic basis, i.e., the lowermost unit, for the Nectarian system is set between 3.92 (Wilhelms 1987; Stöffler and Ryder 2001) and 4.1 Ga (Neukum and Ivanov 1994).
- The Imbrian period is defined by the impact-basin event forming the Imbrium impact crater on the lunar nearside with the Fra Mauro Formation at its base. The Late Imbrian epoch starts with the Orientale basin formation (Hevelius Formation); its upper limit is defined through impact crater sizes only. Two thirds of the lunar mare volcanic deposits are of Late

Imbrian age. Apart from extensive mare-type volcanism, dark mantling deposits are thought to be of Late Imbrian age (Stöffler et al. 2006). Formation of the Orientale basin is suggested to be 3.72 Ga (Stöffler and Ryder 2001) to 3.8 Ga (Wilhelms 1987) or 3.84 Ga (Neukum and Ivanov 1994; Neukum et al. 2001a) depending on the chronology model.

The Early Imbrian epoch covers the time range between Imbrium (Fra Mauro Formation) and Orientale basin formation (Hevelius Formation) corresponding to 3.77 Ga (Stöffler and Ryder 2001) to 3.84 Ga (Wilhelms 1987) or even 3.92 Ga (Neukum and Ivanov 1994; Neukum et al. 2001a) depending on the chronology model. The epoch is characterized by extensive volcanism and impact cratering but without formation of larger impact basins, except for the Schrödinger basin. Many of the light plains have a Lower Imbrian age (Stöffler et al. 2006).

- The Eratosthenian period is defined through the appearance of younger impact craters covering most of other lunar units but showing no signs of rayed ejecta – a criterion that has led to discussions regarding boundary ambiguities (Stöffler et al. 2006; Stöffler and Ryder 2001). Some of the mare basalts were emplaced during the Eratosthenian, but these units are much less extensive than those in the Imbrian period. The basis of the Eratosthenian is generally set to 3.2 Ga (Wilhelms 1987; Stöffler and Ryder 2001; Neukum and Ivanov 1994; Neukum et al. 2001a).
- The Copernican period is defined through the occurrence of rayed craters on the Moon with Copernicus being the most prominent rayed impact crater. These impact craters are superimposed on all other units and show traces of ejecta material all over the Moon despite their relatively small size. Due to its definition, the basis for the Copernican period is not well constrained with ages ranging from 1.1 (Wilhelms 1987) to 1.5 Ga (Neukum and Ivanov 1994; Neukum et al. 2001a) up to 1.1–2.1 Ga (Stöffler and Ryder 2001). The Copernican period continues up to the present time.

Mercury

Mercury's surface is visually comparable to the lunar one as expressed by numerous impact craters and large impact basins, as well as a rich variety of tectonic features probably caused by rapid cooling and tidal despinning (Spudis and Guest 1988; Neukum et al. 2001a). Mercury's surface shows a global dichotomy in terms of major geologic units: the densely cratered terrain (highlands) with interspersed smoother areas (intercrater plains) and the less-densely cratered lowland plains (smooth plains) (Trask and Guest 1975; Spudis and Guest 1988). In contrast to the lunar surface, the smooth plains and highland terrain are comparable in relative albedo. Notwithstanding the surficial resemblance of Mercury and the Moon, crater size frequencies of the heavily cratered highland terrain of Mercury are less than that of the Moon (Spudis and Guest 1988) with a general paucity of impact craters in the 30 km diameter range (Neukum et al. 2001b). The stratigraphic system of Mercury was established by geologic mapping at scales of 1: 5,000,000 in the late 1970s and early 1980s on image data of Mariner 10 flybys.

Mercury's surface resemblance to the Moon led to establishing a stratigraphic system comparable to that of the lunar one with impact events characterizing bases of stratigraphic periods. Mercury's geologic history is therefore subdivided into five periods starting with the pre-Tolstojan as the oldest unit to the Kuiperian as the youngest period (Spudis and Guest 1988).

- The pre-Tolstojan period closely compares to the lunar pre-Nectarian and encompasses geologic units older than 3.97 Ga (Neukum et al. 2001a) to 4.1 Ga (Strom and Neukum 1988) and is related to crater materials and multiring basins as well as intercrater plains (Neukum et al. 2001a; Tanaka and Hartmann 2008; Spudis and Guest 1988).
- During the Tolstojan period which is equivalent to the lunar Nectarian period, the dominant geologic units are the Goya formation that marks the basis of the Tolstojan system and which hosts deposits of the Tolstoj basin as well as materials of small impact basins and

craters. Its base is estimated to be approximately 3.9–4.0 Ga (Spudis and Guest 1988) up to 4.06 Ga (Strom and Neukum 1988) old. Recent age estimates based on new chronology models put the Tolstojan basis at 3.97 Ga ago (Neukum et al. 2001b).

- The Calorian period compares to the lunar Imbrian period and is mainly characterized by Caloris-group units, i.e., mountain material, intermontane plains, hummocky plain, the Calorian plains, as well as impact crater materials and materials of small impact basins. Its time-stratigraphic base is estimated to be in the range of 3.77 Ga (Neukum et al. 2001a), 3.85 Ga (Strom and Neukum 1988) to 3.9 Ga (Spudis and Guest 1988) and is defined by the Caloris impact event that is considered to be the youngest impact basin on Mercury (McCauley et al. 1981).
- The Mansurian period is equivalent to the lunar Eratosthenian period, and its chronostratigraphic base is defined by the impact event of Mansur. With some uncertainties, its crater model age is estimated at 3–3.5 Ga (Spudis and Guest 1988; Strom and Neukum 1988; Neukum et al. 2001a). As for the Kuiperian system, major units are of impact crater origin mainly.
- The Kuiperian period represents the youngest period in Mercury's history, and its base is defined by the age of impact crater Kuiper which occurred ~ 1 Ga ago, equivalent to the lunar Copernican system (Wilhelms 1987; Spudis and Guest 1988; Strom and Neukum 1988; Neukum et al. 2001a). As for the Moon, the period is predominantly characterized by young impact crater materials.

Venus

Radar mapping investigations of Venus' surface in the context of the 1990s Magellan mission have shown that the impact crater frequency on Venus is extremely low. This indicates that the surface as it is observed today has an age of few 100 Ma only (Basilevsky and Head 1998). Widespread volcanism and intensive tectonic disruptions have shaped the surface and deleted most of the older geologic units and the planet's impact crater

record. Consequently, the stratigraphic system is not constrained throughout all of Venus' history and could not be established until the late 1990s, on the basis of photogeologic interpretation of a few selected regions that proved to be statistically significant for establishing a global stratigraphic system (Basilevsky and Head 1998).

The current stratigraphic record represents only 10–20% of Venus' history and covers only 30% of Venus' surface as mapped at scales of 1:3–1:10 M (Basilevsky and Head 1998). Specific geologic time units (periods) are defined mainly on the basis of large impact events and volcanic plain formation events, which helped to establish four major periods: the pre-Fortunian (oldest), Fortunian, Guineverian, and Aurelian (youngest unit). Due to the paucity of impact craters and statistically relevant average estimates of surface ages, absolute ages are usually provided as ratios with respect to the global impact crater frequency ($T = 1.98 \times 10^{-6}$ craters/km²) corresponding to an average surface age of 288 Ma (+311/–98 Ma) according to Strom et al. (1994), 400–800 Ma according to Phillips et al. (1992), or as high as 800 Ma (+800/–400) according to Zahnle and McKinnon (1996) as discussed in Basilevsky and Head (1998) in detail.

- The pre-Fortunian period is not constrained in terms of geologic surface units and spans the time before 1.47 T.
- The Fortunian period is characterized by intensive tectonic deformation with formation of the ancient ► *tessera* terrain that covers about 8% of Venus' surface. Tesserae formation occurred at 1.47 T (1.93–1.01 T in previous estimates) which is considered to form the time basis of the Fortunian period (Basilevsky and Head 1998).
- During the Guineverian period, extensive volcanic plains were formed with a peak at 1.1 T (Tanaka et al. 1997). The period has been proposed to be a supergroup consisting of four plain-forming subunits by Basilevsky and Head (1998). These groups (youngest to oldest unit) follow the proposal by Basilevsky and Head (1998): the Atla Group consisting of relatively undisturbed mafic lava, the Rusalka

- Group lava materials covering up to 75% of Venus' surface, the Lavinia Group characterized by ridged and fractured plains, and the Sigrun Group consisting of densely fractured plain material emplaced as mafic lavas. The Guineverian period covers most of Venus' known geologic record and terminates at around 0.1–0.2 T according to most recent estimates (Basilevsky and Head 1998). A period of younger volcanic activity peaking at 0.4–0.5 T ago with formation of Venus' coronae and rifts as well as formation of large volcanoes at 0.3 T was proposed as a fourth major unit in Tanaka et al. (1997).
- The Aurelian period is characterized by materials associated with the youngest impact craters; its basis is set to 0.1 T containing approximately 10% of Venus' visible cratering record (Tanaka et al. 1997 and references therein) and translating to an age of ~50 Ma using a conservative estimate of the mean surface age.

Mars

On Mars, impact cratering and plain volcanism played a dominant role in shaping the planet's surface throughout history. Additionally, a rich variety of processes related to fluvial, glacial, and eolian resurfacing have significantly contributed to the morphologies that are observed nowadays. Mars' global topography is divided into the densely cratered and old highland terrain in the south and the smooth, less-densely cratered younger northern plains. The subdivision of the stratigraphic system of Mars is based on marker horizons that are formed by plain-forming volcanism (Scott and Carr 1978; Tanaka 1986; Tanaka et al. 1992). Martian geologic time periods are from oldest to youngest: the Noachian (with late, middle, and early epochs), the Hesperian (with a late and early epoch), and the Amazonian (with a late, middle, and early epoch) (Scott and Carr 1978; Tanaka 1986; Tanaka et al. 1992). For Mars, several chronology models were proposed and modified in the course of the availability of new higher-resolution data. Some of these efforts have been combined lately to form the recent chronology model by Hartmann and Neukum (2001). Stratigraphic

boundaries (boundaries of time periods) are slightly different, which has led to a Hartmann model (HM) and a Neukum model (NM).

- A pre-Noachian period is informally established although the Noachian basis is not exposed; however, radiometrically derived ages for the Martian meteorite ALH84001 with a crystallization age of 4.5 Gyr fit into this period (Mittlefehldt 1994).
 - The Noachian system is characterized by the oldest, densely cratered units in the highlands covering a time range of older than 3.97–3.74 Ga for the Noachian system (Tanaka et al. 1992; Hartmann and Neukum 2001). Its basis is defined by highland material of the Noachis Terra located between the Argyre and Hellas Planitia impact basins (Tanaka et al. 1992). The system is generally characterized by Heavy Bombardment impacts, large-scale volcanism peaking in the Tharsis region and the highland volcanic provinces, global tectonism and extensive valley network formation indicating fluvial processes, and a much denser atmosphere and warmer climate.
- The Late Noachian period spans 3.86–3.74 Ga (Hartmann and Neukum 2001) and is characterized by cratered plateau material mainly. During that period, the crustal dichotomy has been morphologically shaped. The Middle Noachian epoch which covers the time span between 3.97 and 3.86 Ga (Hartmann and Neukum 2001) is characterized by cratered highland terrain shaped by impact cratering and the Argyre Planitia impact-basin event. During the late Early Noachian (>3.97 Ga), the Hellas and Isidis impact basins formed, and global volcanism shaped the Tharsis region with the formation of Paterae and Tholi and the circum-Hellas Planitia Highland volcanoes (Tanaka et al. 1992). Recently, the Noachian period was characterized in terms of geochemical alteration by Bibring et al. (2006), suggesting that formation of clay minerals, i.e., phyllosilicates, peaked during the Early and Middle Noachian epochs.
- The Hesperian period is subdivided into the Early and Late Hesperian epochs spanning

3.74–2.9 Ga and is characterized by the Hesperia Planum ridged plain material northeast of the Hellas Planitia impact basin. Impact-cratering rates were significantly lower when compared to the Noachian period, marking the end of the Heavy Bombardment period. Vanishing fluvial activity was replaced by large-scale volcanism in the lowland units (Tanaka et al. 1992 and ref's therein). The disappearance of surface water has led to the assumption that most of the water is stored as permafrost under the surface. Catastrophic release of water led to formation of outflow channels on Mars in the circum-Chryse and eastern Hellas Planitia regions along with formation of the Martian chaotic terrain and the Valles Marineris system (Tanaka et al. 1992). The Hesperian is also characterized by extensive sulfate deposits (Bibring et al. 2006) primarily in the Valles Marineris region. The Early Hesperian period covers the age range of 3.74–3.65 Ga (Hartmann and Neukum 2001) and is defined through the Hesperia Planum ridged plain units. Geologic materials of the Late Hesperian, covering the period between 3.65 and 2.9 Ga (Hartmann and Neukum 2001), are defined through the plain material of the northern plain Vastitas Borealis unit.

- The Amazonian period spans much of Martian history and starts 2.9 Ga ago according to the Hartmann model (HM) and up to 3.31 Ga ago according to the Neukum chronology model (NM). The period is generally defined through processes related to the northern lowland units and plain materials and is characterized by extensive resurfacing processes. Late-stage volcanism and eolian resurfacing shaped large areas of Mars and obliterated older units (Tanaka et al. 1992). The Amazonian also shows late-stage outflow activity in the circum-Chryse Planitia area and an abundance of ice-related surface processes predominantly near the global dichotomy escarpment and circum-Tharsis volcanoes as well as the circum-Hellas/Argyre Planitia regions. Surface alteration by formation of anhydrous ferric oxides led to the planet's characteristic red surface color (Bibring et al. 2006).

The basis of the Upper Amazonian series (Late Amazonian epoch) is defined by flood plain material of the southern Elysium Planitia area and starts 0.3 Ga (HM) to 0.6 Ga (NM) ago (Tanaka 1986; Hartmann and Neukum 2001). Characteristic materials of the Upper Amazonian are predominantly found near the seasonally changing polar caps of Mars and in the young deposits and flow fields delineating the northern hemispheric volcanoes. The Middle Amazonian is defined by the age of Amazonis Planitia lava flow materials (Tanaka 1986; Hartmann and Neukum 2001) and covers the time range between 2.1 and 0.6 Ga (NM) or 1.4–0.3 Ga (HM). The basis for the Early Amazonian epoch is set to 3.3 Ga (NM) to 2.9 Ga (HM) ago and is defined by the smooth plain materials of Acidalia Planitia (Tanaka 1986; Hartmann and Neukum 2001).

Outer Solar System Objects

In contrast to the currently accepted chronology models proposed for the inner planets which are based upon the lunar chronology model with impactors from the asteroid belt, planetary objects in the Outer Solar System are treated in a different way. While one group favors the lunar-like distribution and chronology model for all objects in the Solar System, i.e., lunar-like time dependence of the cratering rate, the second group favors nearly constant cratering rates by cometary impactors. A number of researchers developed lunar-like chronology models for the Jovian and Saturnian system (Shoemaker and Wolfe 1982; Boyce and Plescia 1985; Neukum 1985, 1997). Based on present-day estimates of sizes and dynamics, a constant cratering rate chronology for the icy satellites was put forward with impactors originating in the Kuiper Belt (Zahnle et al. 1998).

The two competing cratering chronology models agree well for old, densely cratered surfaces on the icy satellites, but they are different by more than an order of magnitude for younger, resurfaced units. These issues are discussed in detail in, e.g., Neukum (1997, 1998) and Zahnle et al. (1998).

Imaging data of the Voyager and Galileo missions to the Outer Solar System provided the basis

for impact crater size-frequency statistics and estimates of surface ages of the Galilean satellites. The surface of Europa is considered to be relatively young under assumption of primarily cometary impacts with average ages in the range of 30–70 Ma, as suggested by the less-densely cratered surface of Europa when compared to Callisto or Ganymede (Lucchitta and Soderblom 1982; Zahnle 2003). Employing a lunar-like chronology model with the asteroid belt as main impactor source, surface ages of Europa are in the range of 0.5–1.5 Ga. However, individual units can be as young as approximately 200 Ma or less (Neukum et al. 1998).

The heavily cratered dark plains on Callisto and Ganymede are on the order of 4 Ga and older in both asteroidal and cometary-source chronology models (Neukum et al. 1998; Zahnle et al. 1998, Zahnle 2003). For the younger resurfaced, tectonically disrupted terrain on Ganymede, the lunar-like chronology model gives ages in the range of 3.6–3.9 Ga (Neukum 1997, 1998), while the cometary chronology model gives an age of about 2 Ga (Zahnle 2003) up to few hundred million years (Zahnle et al. 1998).

The densely cratered surfaces of Saturn's icy satellites are estimated to be in the range 3.8–4 Ga old by applying the lunar-like impact chronology model. However, resurfaced units, in particular on Enceladus and Dione, show lower ages at approximately 1.5 Ga (Boyce and Plescia 1985; Neukum 1985).

Current efforts focus on updating existing chronology models with the help of new spacecraft data (e.g., Zahnle 2003) and imply ages far below 1 Ga for the resurfaced terrain on Enceladus and ages as old as 4 Ga for the older terrain, using a constant-rate chronology model with mainly cometary contribution of impactors. Mimas' surface crater impact density is close to saturation, suggestive of an old age, but it lacks larger impact craters beyond 30 km implying a much younger surface age. For Saturn's moon Titan, the small number of observed impact craters suggests very young surface ages. A closer look at the data and impact conditions, however, shows that much of Titan's surface is probably as old as 2 Ga (Jaumann and Neukum 2009).

Definition

Comet 67P/Churyumov–Gerasimenko was the target of the ESA Rosetta mission. This comet was selected because its orbit allowed its exploration by the European spacecraft for a launch scheduled in 2004 and an encounter in 2014. It was also of particular interest since it is thought that the comet had not a long history in the inner Solar System and therefore could contain primitive material kept at low temperature and far from the Sun since the formation of the Solar System.

Overview
